Changes in *fluid volume* also affect the systemic arterial pressure. For example, if there is an excess of sodium and/or water in a person's body, the blood pressure rises through complex physiologic mechanisms that change the venous return to the heart, producing a rise in cardiac output. If the kidneys are functioning adequately, a rise in systemic arterial pressure produces diuresis (excessive voiding) and a fall in pressure. Pathologic conditions change the pressure threshold at which the kidneys excrete sodium and water, thereby altering the systemic arterial pressure.

The *renin-angiotensin-aldosterone* system also regulates blood pressure (see discussion in [Chapter 13](#)). The kidney produces renin, an enzyme that acts on angiotensinogen (a plasma protein substrate) to split off angiotensin I, which is converted by an enzyme in the lung to form angiotensin II. Angiotensin II has strong vasoconstrictor action on blood vessels and is the controlling mechanism for aldosterone release. Aldosterone then works on the collecting tubules in the kidneys to reabsorb sodium. Sodium retention inhibits fluid loss, thus increasing blood volume and subsequent blood pressure.

Inappropriate secretion of renin may cause increased peripheral vascular resistance in patients with hypertension. When the blood pressure is high, renin levels should decrease because the increased renal arteriolar pressure usually inhibits renin secretion. However, for most people with essential hypertension, renin levels remain normal.

The process of *vascular autoregulation*, which keeps perfusion of tissues in the body relatively constant, appears to be important in causing hypertension. However, the exact mechanism of how this system works is poorly understood.

Classifications of Hypertension

In 2003 the JNC made significant changes in classifying blood pressure in adults. The classification for “**normal**” **adult blood pressure** is less than 120 mm Hg systolic *and* less than 80 mm Hg diastolic. Adults with a blood pressure (BP) of 120 to 139 mm Hg systolic *or* 80 to 89 mm Hg diastolic,

TABLE 38-3 BLOOD PRESSURE CLASSIFICATION

CLASSIFICATION	BLOOD PRESSURE MEASUREMENT	BLOOD PRESSURE READINGS
Normal	Systolic <i>and</i> diastolic	<120 mm Hg <80 mm Hg
Prehypertension	Systolic <i>or</i> diastolic	120-139 mm Hg 80-89 mm Hg
Stage 1: Hypertension	Systolic <i>or</i> diastolic	140-159 mm Hg 90-99 mm Hg
Stage 2: Hypertension	Systolic <i>or</i> diastolic	≥160 mm Hg ≥100 mm Hg

From Joint National Committee. (2003). The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. NIH Publication No. 03-5233. Bethesda, MD: National Heart, Lung, and Blood Institute.

TABLE 38-4 MEETING HEALTHY PEOPLE 2020 OBJECTIVES

Heart Disease and Stroke

Selected objectives retained from *Healthy People 2010*:

- Increase the proportion of adults with high blood pressure who are taking action to help control their blood pressure.
- Increase the proportion of adults who have had their blood pressure measured within the preceding 2 years and can state whether their blood pressure was normal or high.

Selected objectives retained but modified from *Healthy People 2010*:

- Reduce the proportion of persons in the population with hypertension.
- Increase the proportion of adults with prehypertension who meet the recommended guidelines for:
 - a. Body mass index (BMI)
 - b. Saturated fat consumption
 - c. Sodium intake
 - d. Physical activity
 - e. Moderate alcohol consumption
- Increase the proportion of adults with hypertension who meet the [above] recommended guidelines.

New objectives for Healthy People 2020:

- Increase the proportion of adults with hypertension who are taking the recommended medications to decrease their blood pressure.

Data from www.healthypeople.gov/2020.

considered “normal” under previous guidelines, are classified as *prehypertensive*. These patients need lifestyle changes to prevent cardiovascular complications ([Table 38-3](#)). The relationship between hypertension and cardiovascular events is direct and independent of other risk factors. The higher the patient's blood pressure is, the greater the chance for coronary, cerebral, renal, and peripheral vascular disease.

Control of hypertension has resulted in major decreases in cardiovascular morbidity and mortality. The *Healthy People 2020* campaign includes a number of objectives related to hypertension to decrease cardiovascular mortality ([Table 38-4](#)).

Hypertension can be essential (primary) or secondary ([Table 38-5](#)). Essential hypertension is the most common classification. Sustained BP elevation in patients with essential hypertension results in damage to vital organs by causing

TABLE 38-5 ETIOLOGY OF HYPERTENSION

Essential (Primary)	Secondary
- Family history of hypertension - African-American ethnicity - Hyperlipidemia - Smoking - Older than 60 years or postmenopausal - Excessive sodium and caffeine intake - Overweight/obesity - Physical inactivity - Excessive alcohol intake - Low potassium, calcium, or magnesium intake - Excessive and continuous stress	- Kidney disease - Primary aldosteronism - Pheochromocytoma - Cushing's disease - Coarctation of the aorta - Brain tumors - Encephalitis - Pregnancy - Drugs: - Estrogen (e.g., oral contraceptives) - Glucocorticoids - Mineralocorticoids - Sympathomimetics

medial hyperplasia (thickening) of the arterioles. As the blood vessels thicken and perfusion decreases, body organs are damaged. These changes can result in myocardial infarctions, strokes, peripheral vascular disease (PVD), or renal failure.

Specific disease states and drugs can increase a person's susceptibility to hypertension. A person with this type of elevation in blood pressure has **secondary hypertension**.

Isolated systolic hypertension (ISH) is a major health threat, especially for older adults. It is defined as a systolic BP (SBP) reading at or above 140 with a diastolic BP (DBP) below 90. For years, emphasis was placed on the diastolic BP (DBP) reading and attempts were made to lower this number to under 80. However, as people age, the systolic BP (SBP) becomes more significant because it is a better indicator than DBP of risk for heart disease and stroke. Research has shown that DBP rises until age 55 years and then declines, whereas SBP continues to rise. New research demonstrates a significant association between isolated systolic hypertension and peripheral vascular disease (Safar et al., 2009). In older adults, isolated systolic hypertension is the most common form of hypertension.

Malignant hypertension is a severe type of elevated blood pressure that rapidly progresses. A person with this health problem usually has symptoms such as morning headaches, blurred vision, and dyspnea and/or symptoms of uremia (accumulation in the blood of substances ordinarily eliminated in the urine). Patients are often in their 30s, 40s, or 50s with their systolic blood pressure greater than 200 mm Hg. The diastolic blood pressure is greater than 150 mm Hg or greater than 130 mm Hg when there are pre-existing complications. Unless intervention occurs promptly, a patient with malignant hypertension may experience renal failure, left ventricular failure, or stroke.

Etiology and Genetic Risk

Essential hypertension can develop when a patient has any one or more of the risk factors listed in Table 38-5.

Renal disease is one of the most common causes of *secondary* hypertension. Hypertension can develop when there is any sudden damage to the kidneys. Renovascular hypertension is associated with narrowing of one or more of the main arteries carrying blood directly to the kidneys, known as *renal artery stenosis* (RAS). Many patients have been able to reduce

the use of their antihypertensive drugs when the narrowed arteries are dilated through angioplasty with stent placement. All patients requiring three or four categories of antihypertensive drugs at high doses should be screened for RAS.

Dysfunction of the adrenal medulla or the adrenal cortex can also cause secondary hypertension. *Adrenal-mediated hypertension* is due to primary excesses of aldosterone, cortisol, and catecholamines. In *primary aldosteronism*, excessive aldosterone causes hypertension and hypokalemia (low potassium levels). It usually arises from benign adenomas of the adrenal cortex. *Pheochromocytomas* originate most commonly in the adrenal medulla and result in excessive secretion of catecholamines, resulting in life-threatening high blood pressure. In *Cushing's syndrome*, excessive glucocorticoids are excreted from the adrenal cortex. The most common cause of Cushing's syndrome is either adrenocortical hyperplasia or adrenocortical adenoma.

Drugs that can cause secondary hypertension include estrogen, glucocorticoids, mineralocorticoids, sympathomimetics, cyclosporine, and erythropoietin. The use of estrogen-containing oral contraceptives is likely the most common cause of secondary hypertension in women. Drugs that cause hypertension are discontinued to reverse this problem.

Incidence/Prevalence

One in every three American adults has high blood pressure or is being treated for hypertension (AHA, 2010). The disease shortens life expectancy. A higher percentage of men than women have hypertension until age 45 years. From 45 to 54 years, women have a slightly higher percentage of hypertension than men. After age 54 years, women have a much higher percentage of the disease (AHA, 2010). The causes for these differences are not known.

CULTURAL AWARENESS

The prevalence of hypertension in African Americans in the United States is among the highest in the world and is constantly increasing. When compared with Euro-Americans, they develop high BP earlier in life, making them much more likely to die from strokes, heart disease, and kidney disease (AHA, 2010). The exact reasons for these differences is not known, but genetics and environmental factors may play a role. Efforts to raise awareness of hypertension within African-American communities, including the importance of receiving treatment and controlling blood pressure, have been somewhat successful. Geographic differences still exist (Lloyd-Jones et al., 2010).

Health Promotion and Maintenance

Teach patients ways to decrease risk factors for hypertension, which are the same as those for coronary artery disease (CAD). Risk factor prevention and lifestyle changes are discussed in Chapter 40.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

During history taking, review the patient's risk factors for hypertension. Collect data on the patient's age; ethnic origin or race; family history of hypertension; average dietary intake

FIG. 38-2 Blood pressure screening during history and physical examination.

of calories, sodium- and potassium-containing foods, and alcohol; and exercise habits. Also assess any past or present history of kidney or cardiovascular disease and current use of drug therapy or illicit drugs.

Physical Assessment/Clinical Manifestations

When a diagnosis of hypertension is made, most people have no symptoms. However, patients may experience headaches, facial flushing (redness), dizziness, or fainting as a result of the elevated blood pressure. Obtain blood pressure readings in both arms. Two or more readings may be taken at each visit (Fig. 38-2). Some patients have high blood pressure due to anxiety associated with visiting a health care provider. Be sure to take an accurate blood pressure by using an appropriate-size cuff. Anderson et al. (2010) found that forearm blood pressure measurements are as accurate as upper arm blood pressures, especially in patients who are obese. In ambulatory care settings, such as clinics and office practices, wrist blood pressure measurements can be used.

To detect postural (orthostatic) changes, take readings with the patient in the supine (lying) or sitting position and at least 2 minutes later when standing. **Orthostatic hypotension** is a decrease in blood pressure (20 mm Hg systolic and/or 10 mm Hg diastolic) when the patient changes position from lying to sitting.

Funduscopic examination of the eyes to observe vascular changes in the retina is done by a skilled practitioner. The appearance of the retina can be a reliable index of the severity and prognosis of hypertension.

Physical assessment is helpful in diagnosing several conditions that produce secondary hypertension. The presence of abdominal bruits is typical of patients with renal vascular disease. Tachycardia, sweating, and pallor may suggest a pheochromocytoma (adrenal medulla tumor). Coarctation of the aorta is evidenced by elevation of blood pressure in the arms, with normal or low blood pressure in the lower extremities. Femoral pulses are also delayed or absent.

Psychosocial Assessment

Assess for psychosocial stressors that can worsen hypertension and affect the patient's ability to adhere to treatment. Evaluate job-related, economic, and other life stressors, as well as the patient's response to these stressors. Some patients may have difficulty coping with the lifestyle changes needed to control hypertension. Be sure to assess past coping strategies.

Diagnostic Assessment

Although no laboratory tests are diagnostic of essential hypertension, several laboratory tests can assess possible causes of secondary hypertension. Kidney disease can be diagnosed by the presence of protein, red blood cells, pus cells, and casts in the urine; elevated levels of blood urea nitrogen (BUN); and elevated serum creatinine levels. The creatinine clearance test directly indicates the glomerular filtration ability of the kidneys. The normal value is 107 to 139 mL/min for men and 87 to 107 mL/min for women (Pagana & Pagana, 2010). Decreased levels indicate kidney disease.

Urinary test results are positive for the presence of catecholamines in patients with a pheochromocytoma (tumor of the adrenal medulla). An elevation in levels of serum corticoids and 17-ketosteroids in the urine is diagnostic of Cushing's disease.

No specific x-ray studies can diagnose hypertension. Routine chest radiography may help recognize cardiomegaly (heart enlargement).

An electrocardiogram (ECG) determines the degree of cardiac involvement. Left atrial and ventricular hypertrophy is the first ECG sign of heart disease resulting from hypertension. Left ventricular remodeling can be detected on the 12-lead ECG (see Chapter 40 for discussion of remodeling).

ANALYSIS

The priority problems for patients with hypertension are:

1. Need for health teaching related to the plan of care for hypertension management
2. Risk for nonadherence related to side effects of drug therapy and necessary changes in lifestyle

PLANNING AND IMPLEMENTATION

Health Teaching

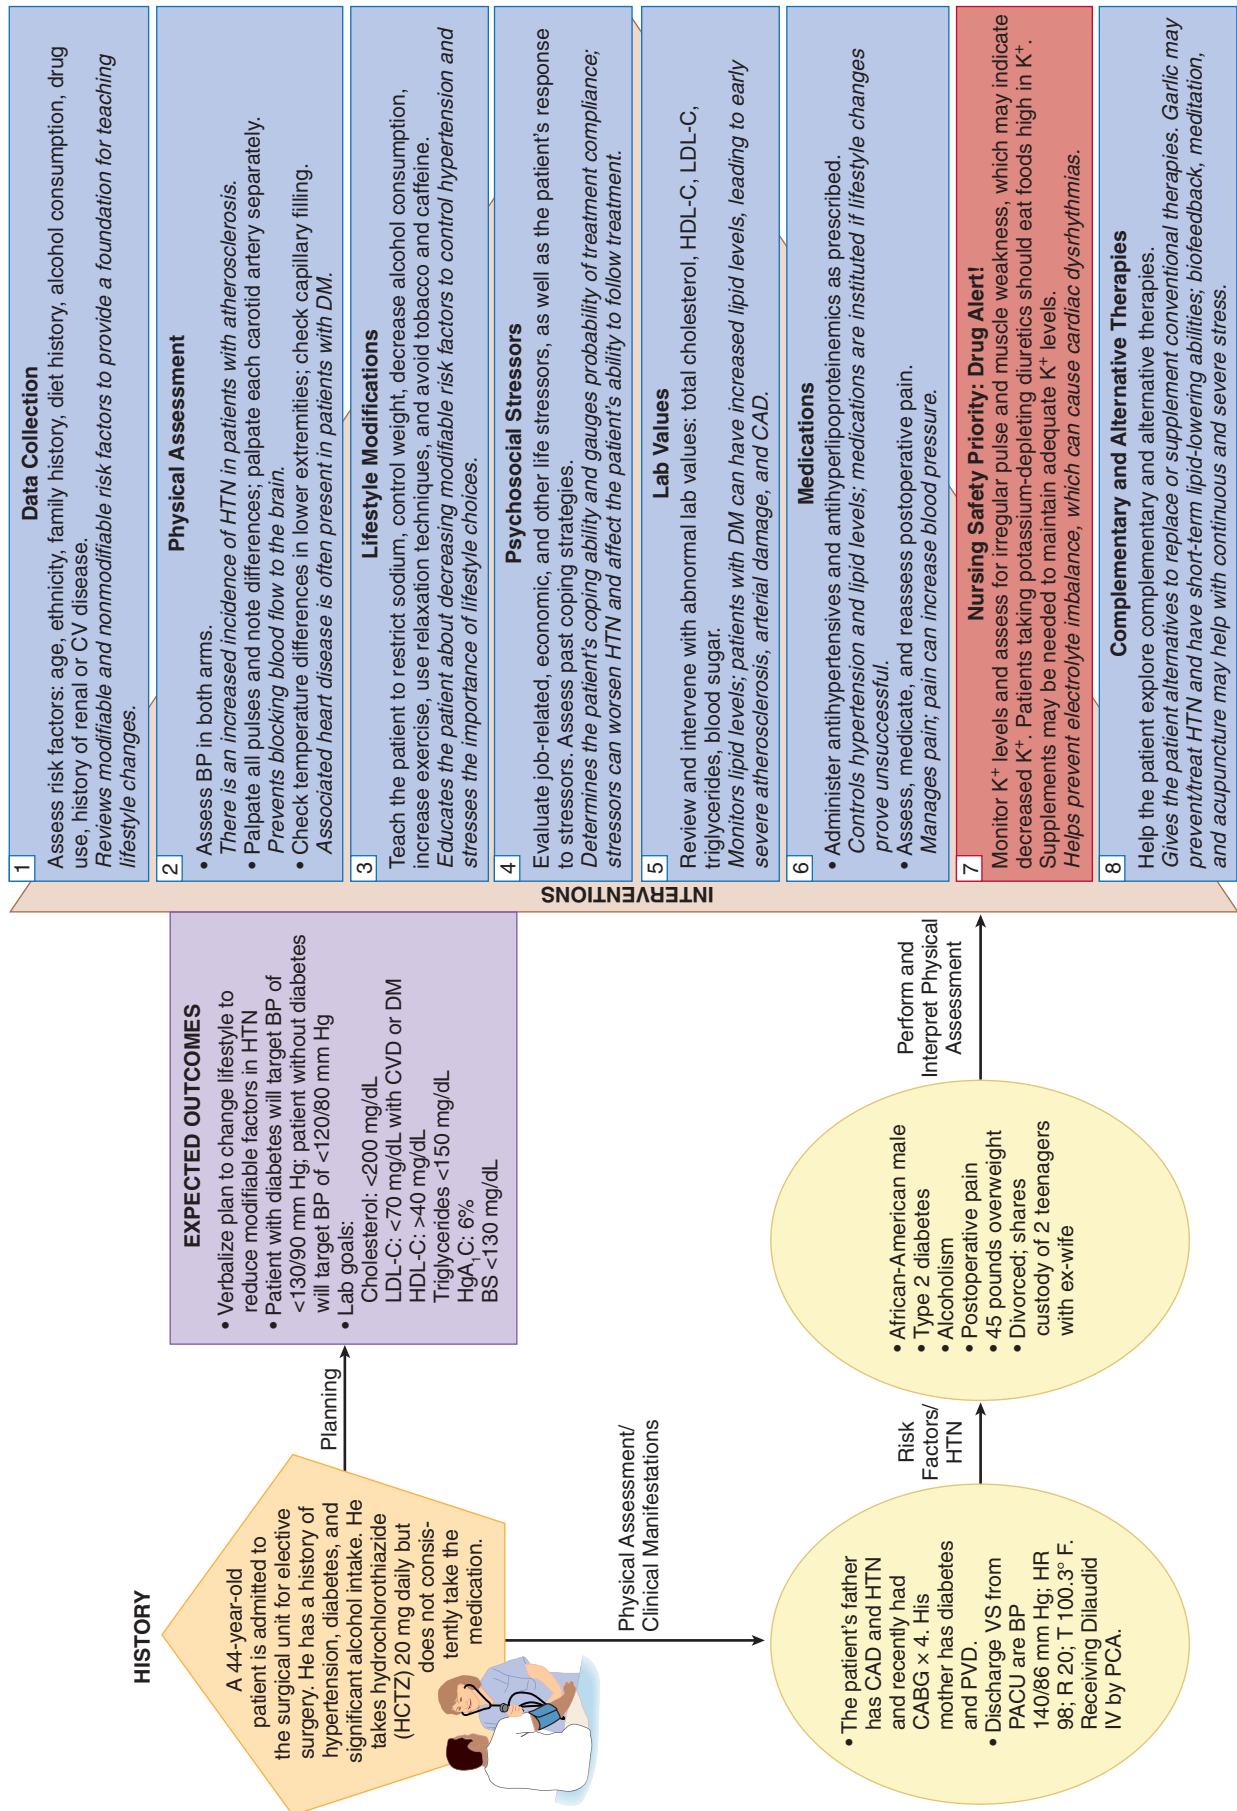

Planning: Expected Outcomes. The patient with hypertension is expected to verbalize his or her individualized plan of care for hypertension (see the Concept Map on Hypertension on p. 779).

Interventions. Lifestyle changes are considered the foundation of hypertension control. If these changes are unsuccessful, the health care provider considers the use of antihypertensive drugs. There is no surgical treatment for essential hypertension. However, surgery may be indicated for certain causes of secondary hypertension, such as renal vascular disease, coarctation of the aorta, and pheochromocytoma.

Lifestyle Changes. In collaboration with the health care team, teach the patient to:

- Restrict sodium intake in the diet
- Reduce weight, if overweight or obese
- Use alcohol sparingly

Concept Map: Hypertension

- Exercise 5 days a week
- Use relaxation techniques to decrease stress
- Avoid tobacco and caffeine

Strategies to help patients make these changes are discussed in [Chapter 40](#).

Complementary and Alternative Therapies. Garlic has been used for centuries for a number of health problems, but evidence to support its use to prevent hypertension is controversial. Evidence by consensus and case reports does support garlic's cholesterol-lowering ability and its ability to decrease blood pressure in patients with hypertension ([National Center for Complementary and Alternative Medicine, 2010](#)). Teach patients to check with their health care provider before starting garlic or any herbal therapy because of possible side effects and interactions with other herbs, foods, or drugs. Garlic can affect the liver and cause bleeding in some patients, especially if they have invasive procedures such as surgery.

Some patients have also had success with biofeedback, meditation, and acupuncture as part of their overall management plan. These methods may be most useful as adjuncts for patients who experience continuous and severe stress.

Drug Therapy. Drug therapy is individualized for each patient, with consideration given to culture, age, other existing illness, severity of blood pressure elevation, and cost of drugs and follow-up. Once-a-day drug therapy is best, especially for the older adult, because the more doses required each day, the higher the risk that a patient will not follow the treatment regimen. However, many patients with hypertension need two or more drugs to adequately control blood pressure.

In the largest hypertensive trial done to date, Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), the use of diuretics has been practically unmatched in preventing the cardiovascular complications of hypertension. Calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, and aldosterone receptor antagonists may also be given. Examples of commonly used drug classes for hypertension are listed in [Chart 38-1](#).

Diuretics. Diuretics are the first type of drugs for managing hypertension ([Cranwell-Bruce, 2008](#)). Three basic types of diuretics are used to decrease blood volume and lower blood pressure in order of how commonly they are prescribed:

- Thiazide (low-ceiling) diuretics, such as hydrochlorothiazide (HydroDIURIL, Microzide, Oretic, Urozide ☼), inhibit sodium, chloride, and water reabsorption in the distal tubules while promoting potassium, bicarbonate, and magnesium excretion. However, they decrease calcium excretion, which helps

prevent kidney stones and bone loss ([Cranwell-Bruce, 2008](#)). Because of the low cost and high effectiveness of thiazide-type diuretics, they are usually the drugs of choice for patients with uncomplicated hypertension. These drugs can be prescribed as a single agent or in combination with other classes of drugs.

- Loop (high-ceiling) diuretics, such as furosemide (Lasix, Furoside ☼) and torsemide (Demadex), inhibit sodium, chloride, and water reabsorption in the ascending loop of Henle and promote potassium excretion.

CONSIDERATIONS FOR OLDER ADULTS

Use loop diuretics with caution in older adults because they can cause dehydration and orthostatic hypotension. These complications increase the patient's risk for falls. Teach families to monitor for and report patient dizziness, falls, or confusion to the health care provider as soon as possible and discontinue the medication.

- Potassium-sparing diuretics, such as spironolactone (Aldactone, Novospiron ☼), triamterene (Dyrenium), and amiloride (Midamor), act on the distal renal tubule to inhibit reabsorption of sodium ions in exchange for potassium, thereby *retaining* potassium in the body. When used, they are typically in combination with another diuretic or antihypertensive drug to *conserve* potassium.

Frequent voiding caused by any type of diuretic may interfere with daily activities. Teach patients to take their diuretic in the morning rather than at night to prevent nocturia.

! NURSING SAFETY PRIORITY

Drug Alert

The most frequent side effect associated with *thiazide and loop diuretics* is **hypokalemia** (low potassium level). Monitor serum potassium levels, and assess for irregular pulse and muscle weakness, which may indicate hypokalemia. Teach patients taking potassium-depleting diuretics to eat foods high in potassium, such as bananas and orange juice. Many people also need a potassium supplement to maintain adequate serum potassium levels.

Assess for **hyperkalemia** (high potassium level) for patients taking potassium-sparing diuretics, such as spironolactone. Like hypokalemia, an increased potassium level can also cause weakness and irregular pulse. These electrolyte imbalances are described in detail in [Chapter 13](#).

Other Antihypertensive Drugs. Calcium channel blockers such as verapamil hydrochloride (Calan, Nu-Verap ☼) and amlodipine (Norvasc) lower blood pressure by interfering with the transmembrane flux of calcium ions. This results in vasodilation, which *decreases* blood pressure. These drugs also block SA and AV node conduction, resulting in a decreased heart rate. Calcium channel blockers are most effective in older adults and African Americans ([Cranwell-Bruce, 2008](#)).

A newer calcium channel blocker, clevidipine butyrate (Cleviprex), is available only in IV form and must be administered using an infusion pump. This drug is indicated when oral therapy is not possible and is most often used for hypertensive urgency or severe hypertension. The most common side effects are headache and nausea. Monitor the patient's blood pressure frequently to check for hypotension. A dosage

! NURSING SAFETY PRIORITY

Drug Alert

Teach men that they may experience decreased libido (desire for sex) and decreased sexual performance when taking thiazides. Thiazides should be used with caution in patients with diabetes mellitus because they can interfere with serum glucose levels. Caution is also indicated for patients with gout or a history of significant hyponatremia (decreased serum sodium level) because these problems can worsen when thiazides are taken.

CHART 38-1 COMMON EXAMPLES OF DRUG THERAPY

Hypertension Management

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Diuretics			
Hydrochlorothiazide (HCTZ) (Microzide, Oretic, Urozide) 25-100 mg orally daily	Low-ceiling diuretic that inhibits Na ⁺ , Cl ⁻ , and water reabsorption in the distal tubules of the kidney.	Teach patient to eat foods high in K ⁺ and have follow-up lab tests to monitor electrolyte levels. Teach older adults to rise slowly from chair or bed. Use with caution for patients with diabetes. Use with caution for patients with gout. Report weakness or dizziness or new-onset confusion to the health care provider. Same as for HCTZ, except safer to give to patients with diabetes and gout.	Drug causes K ⁺ and Mg ²⁺ excretion. Drug causes diuresis, which can cause orthostatic hypotension. Drug can affect glucose control. Drug can cause uric acid retention. Drug can cause hypovolemia, dehydration, and hypokalemia. Same as for HCTZ.
Furosemide (Lasix, Furoside) 40-600 mg orally daily	High-ceiling diuretic that inhibits Na ⁺ , Cl ⁻ , and water reabsorption in the kidney's loop of Henle.		
Spironolactone (Aldactone, Novo-Spiron) 50-400 mg orally daily	Acts on distal tubules of kidneys to inhibit reabsorption of Na ⁺ in exchange for K ⁺ .	Teach patients to decrease intake of foods high in potassium and have follow-up lab tests for electrolyte levels. Teach patients to report weakness and irregular pulse to health care provider.	Drug causes K ⁺ retention in the body. These symptoms may indicate hyperkalemia.
Calcium Channel Blockers			
Verapamil (Calan, Nu-Verap) Up to 480 mg orally in 3 divided doses; Extended-release form (ER) also available as 240-480 mg orally daily	Interferes with flux of calcium ions to cause vasodilation, which lowers blood pressure.	Monitor pulse and blood pressure before taking each day; do not take if pulse is less than 60 or systolic BP is below 100 mm Hg without contacting health care provider. Teach patients and their families that patients should avoid grapefruit juice when taking calcium channel blockers. *Same as above for verapamil, but safe to drink grapefruit juice.	Drug slows SA and AV conduction in the heart, thus decreases heart rate; vasodilation causes decreased blood pressure. Grapefruit juice can enhance the action of the drug. *Same as above for verapamil, but safe to drink grapefruit juice.
Amlodipine (Norvasc) 5-10 mg orally daily	Same as above for verapamil.		
Angiotensin-Converting Enzyme (ACE) Inhibitors			
Lisinopril (Prinivil, Zestril) 10-80 mg orally daily	Blocks action of ACE in converting angiotensin I to angiotensin II (vasoconstrictor).	Report nagging cough to health care provider. Monitor blood pressure carefully, especially orthostatic checks; remind patients to move slowly from sitting to standing to prevent dizziness and possible falls. Do not give drug if systolic blood pressure is below 100 without checking with health care provider. Monitor blood pressure as described above for lisinopril.	Cough is a common and annoying side effect, and drug should be discontinued if it occurs. Drug prevents vasoconstriction by angiotensin II resulting in vasodilation and decreased blood pressure.
Enalapril (Vasotec) 10-40 mg orally daily or in divided doses; also available in IV form	Same as above for lisinopril.		Same as above for lisinopril.

Continued

CHART 38-1 COMMON EXAMPLES OF DRUG THERAPY

Hypertension Management—cont'd

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Angiotensin II Receptor Blockers (ARBs)			
Valsartan (Diovan) 80-320 mg orally daily	Blocks binding of angiotensin II to receptor sites in vascular smooth muscle and adrenal glands.	Teach patients to avoid foods high in potassium. Monitor blood pressures to ensure that hypotension does not occur. Do not take drug if systolic BP is below 100 without checking with a health care provider. Same as above for valsartan.	ARBs can cause hyperkalemia, especially when combined with other antihypertensive drugs. Vasodilation causes decreased blood pressure. Same as above for valsartan.
Losartan (Cozaar) 25-100 mg orally daily or in divided doses twice a day	Same as above for valsartan.		
Aldosterone Receptor Antagonists			
Eplerenone (Inspra) 25-50 mg orally daily	Blocks aldosterone binding at receptor sites in kidney, heart, blood vessels, and brain to inhibit sodium reabsorption by the kidneys.	Teach patients to follow up with lab tests as scheduled; decrease food intake of high potassium foods. Avoid taking the drug with grapefruit juice and St. John's wort. Avoid taking the drug with itraconazole (Sporanox) and ketoconazole (Nizoral). Check with the pharmacist about interactions with other drugs or herbs that the patient is taking.	Drug can cause increases in K ⁺ and triglycerides and a decreased Na ⁺ . Grapefruit juice and St. John's wort increase the risk for adverse drug events when taking eplerenone. These drugs interact with eplerenone. Drug interacts with many other drugs and herbs and is either not prescribed or drug dosage is adjusted.
Beta-Adrenergic Blockers			
Metoprolol (Toprol, Toprol XL, Lopressor, Betaloc  100-400 mg orally daily or in divided doses (one dose daily for XL form)	Cardioselective drugs block beta ₁ receptors in the heart and peripheral blood vessels.	Monitor carefully for orthostatic hypotension; teach patients to rise slowly from the sitting position to prevent dizziness; do not take drug if systolic BP is below 100 without contacting the health care provider. Monitor pulse rate every day; do not take drug if pulse is below 60 without contacting the health care provider. Teach the patient that the drug can cause fatigue, depression, and sexual dysfunction; report any of these problems to the health care provider. Use the drug with caution in patients who are diabetic.	Orthostatic hypotension is a common adverse effect of the drug and can contribute to falls and confusion, especially in older adults. The beta ₁ -blocking action of the drug decreases the rate, contractility, and output of the heart. The drug has many side and adverse effects because of its potent action. Because of the sympathetic blocking action of the drug, glucose production may be affected. Same as above for metoprolol.
Atenolol (Tenormin, Apo-Atenol  50-100 mg orally daily	Same as above for metoprolol.	Same as above for metoprolol.	Same as above for metoprolol.
Renin Inhibitors			
Aliskiren (Tekturna) 150-300 mg orally daily	Inhibits renin production, which prevents conversion of angiotensinogen to angiotensin I; decreased vasoconstriction, peripheral resistance, and cardiac output result.	Teach patients that side effects (cough and diarrhea) are not common; in a few cases, respiratory distress has occurred.	Drug is relatively safe with few side effects.

increase of 1 to 2 mg/hr generally produces an additional 2- to 4-mm Hg decrease in systolic blood pressure.

Angiotensin-converting enzyme (ACE) inhibitors, also known as the “*pril*” drugs, are also used as single or combination agents in the treatment of hypertension. These drugs block the action of the angiotensin-converting enzyme as it attempts to convert angiotensin I to angiotensin II, one of the most powerful vasoconstrictors in the body. This action also decreases sodium and water retention and lowers peripheral vascular resistance, both of which lower blood pressure. ACE inhibitors include captopril (Capoten), lisinopril (Prinivil, Zestril), and enalapril (Vasotec). The most common side effect of this group of drugs is a nagging, dry cough. Teach patients to report this problem to their health care provider as soon as possible. If a cough develops, the drug is discontinued.

! NURSING SAFETY PRIORITY

Drug Alert

Instruct the patient receiving an ACE inhibitor for the first time to get out of bed slowly to avoid the severe hypotensive effect that can occur with initial use. Orthostatic hypotension may occur with subsequent doses, but it is less severe. If dizziness continues or there is a significant decrease in the systolic blood pressure (more than a change of 20 mm Hg), notify the health care provider or teach the patient to notify his or her provider. *The older patient is at the greatest risk for postural hypotension because of the cardiovascular changes associated with aging.*

Angiotensin II receptor antagonists, also called *angiotensin II receptor blockers (ARBs)* or the *-sartan drugs*, make up a group of drugs that selectively block the binding of angiotensin II to receptor sites in the vascular smooth muscle and adrenal tissues by competing directly with angiotensin II but not inhibiting ACE (Cranwell-Bruce, 2008). Examples of drugs in this group are candesartan (Atacand), valsartan (Diovan), and losartan (Cozaar). ARBs can be used alone or in combination with other antihypertensive drugs. These drugs are excellent options for patients who report a nagging cough associated with ACE inhibitors. In addition, these drugs do not require initial adjustment of the dose for older adults or for any patient with renal impairment. Like the ACEs, the ARBs are not as effective in African Americans unless these drugs are taken with diuretics or another category such as a beta blocker or calcium channel blocker (AHA, 2010).

Aldosterone receptor antagonists block the hypertensive effect of the mineralocorticoid hormone *aldosterone*. Aldosterone increases sodium reabsorption by the kidney and is a significant contributor to hypertension, cardiac and vascular remodeling, and heart failure. Eplerenone (Inspra) lowers blood pressure by blocking aldosterone binding at the mineralocorticoid receptor sites in the kidney, heart, blood vessels, and brain. Generally well tolerated, eplerenone has dose-related adverse effects of hypertriglyceridemia, hyponatremia, and hyperkalemia. Using ACE inhibitors or ARBs at the same time increases the risk for hyperkalemia. Therefore monitor potassium levels carefully, initially every 2 weeks for the first few months and then monthly thereafter.

Beta-adrenergic blockers, identified by the ending *-olol*, are categorized as cardioselective (working only on the cardiovascular system) and non-cardioselective. Cardioselective beta blockers, affecting only beta-1 receptors, may be prescribed to lower blood pressure by blocking beta receptors in

! NURSING SAFETY PRIORITY

Drug Alert

When taking eplerenone, itraconazole (Sporanox) and ketoconazole (Nizoral) should not be taken. Drug interactions are common. Patients taking erythromycin, fluconazole (Diflucan), saquinavir (Fortovase), and verapamil (Calan) can take eplerenone but with a reduction in dosage by half to 25 mg daily. Teach patients that grapefruit juice and the popular herb *St. John's wort* can also increase the chance of adverse effects. Similar to all antihypertensives, remind patients not to get up quickly, drive, or climb stairs until they adjust to the effects of the drug.

the heart and peripheral vessels. By blocking these receptors, the drugs decrease heart rate and myocardial contractility. Teach patients about common side effects of beta blockers, including fatigue, weakness, depression, and sexual dysfunction. The potential for side effects depends on the “selective” blocking effects of the drug. Atenolol (Tenormin, Apo-Atenol), bisoprolol (Zebeta), and metoprolol (Lopressor, Toprol, Toprol-XL, Betaloc) are commonly used cardioselective beta blockers for hypertension.

Patients with diabetes who take beta blockers may not have the usual manifestations of hypoglycemia because the sympathetic nervous system is blocked. The body's responses to hypoglycemia such as gluconeogenesis may also be inhibited by certain beta blockers.

Beta blockers are the drug of choice for hypertensive patients with ischemic heart disease (IHD) because the heart is the most common target of end-organ damage with hypertension. If this drug is not tolerated, a long-acting calcium channel blocker can be used. In patients with unstable angina or myocardial infarction (MI), beta blockers or calcium channel blockers should be used initially in combination with ACE inhibitors or ARBs, with addition of other drugs if needed to control the blood pressure. Best practice for controlling hypertension in post-myocardial infarction (MI) patients includes a combination therapy of beta blockers, ACE inhibitors or ARBs (not as common), and aldosterone antagonists plus intense management of lipids and the use of aspirin. Low-dose aspirin should be considered only once the blood pressure is controlled because of the increased risk for hemorrhagic stroke in patients with uncontrolled hypertension. Patients who are prehypertensive may also benefit from low-dose daily aspirin (Hermida et al., 2009).

Renin inhibitors are effective for mild to moderate hypertension. Aliskiren (Tekturna) is an example and can be used alone or with a thiazide diuretic. Renin is an enzyme produced in the kidneys that causes vasoconstriction, increases peripheral resistance, and increases cardiac output. The result is an increase in blood pressure. Renin inhibitors prevent renin from producing this action. Side effects are minimal and not common, although respiratory distress may occur.

Central alpha agonists act on the central nervous system, preventing reuptake of norepinephrine and resulting in lower peripheral vascular resistance and blood pressure. Clonidine (Catapres) is most commonly used in this drug classification and is usually given as a transdermal patch, providing control of blood pressure for as long as 7 days. Side effects include sedation, postural hypotension, and impotence. This group of drugs is not indicated for first-line management of hypertension but may be added for selected patients.

Alpha-adrenergic antagonists, such as prazosin (Mini-press), doxazosin (Cardura), and terazosin (Hytrin), dilate the arterioles and veins. These drugs can lower blood pressure quickly, but their use is limited because of frequent and both-ersome side effects.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is prescribed hydrochlorothiazide (Microzide) for control of hypertension. What health teaching will the nurse provide before the client begins therapy?

- A. "You may develop a slower pulse rate."
- B. "You may notice some swelling in your feet."
- C. "You may develop a nagging cough."
- D. "Your diet should include foods high in potassium."

Promoting Adherence to the Plan of Care

Planning: Expected Outcomes. The patient with hypertension is expected to adhere to the plan of care, including making necessary lifestyle changes.

Interventions. Patients who require medications to control essential hypertension usually need to take them for the rest of their lives. Some patients stop taking them because they have no symptoms and have troublesome side effects.

In the hospital setting, collaborate with the pharmacist, as needed, to discuss the outcomes of therapy with the patient, including potential side effects. Assist the patient in tailoring the therapeutic regimen to his or her lifestyle and daily schedule.

Patients who do not adhere to antihypertensive treatment are at a high risk for target organ damage and *hypertensive urgency or crisis* (causes organ damage, such as kidney or heart [target organs]) (Chart 38-2). Patients in hypertensive crisis are admitted to critical care units, where they receive IV antihypertensive therapy such as nitroprusside (Nipride), nicardipine (Cardene IV), fenoldopam (Corlopam), or labetalol (Normodyne). These drugs act quickly as vasodilators to decrease blood pressure (BP). When the patient's blood pressure stabilizes, oral antihypertensive drugs are given (Horne & Gordon, 2009).

Community-Based Care

Home Care Management

Hypertension is a chronic illness. Allow patients to verbalize feelings about the disease and its treatment. Emphasize that their involvement in the collaborative plan of care can lead to control of the disease and can prevent complications.

Some patients do not adhere to their drug therapy regimen at home because they have no symptoms or they simply forget to take their drugs. Others may think they are not sick enough to need medication. Some patients may assume that once their blood pressure returns to normal levels, they no longer need treatment. They may also stop taking their drugs because of side effects or cost. Develop a plan with the patient, and identify ways to encourage adherence to the plan of care.

Teaching for Self-Management

Schmid et al. (2009) found that patient education is essential to help patients become successful in managing their blood pressure (see the Evidence-Based Practice box on p. 785).

CHART 38-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of Patients with Hypertensive Urgency or Crisis

Assess

- Severe headache
- Extremely high blood pressure (BP)
- Dizziness
- Blurred vision
- Shortness of breath
- Epistaxis (nosebleed)
- Severe anxiety

Intervene

- Place patient in a semi-Fowler's position.
- Administer oxygen.
- Start IV of 0.9% normal saline (NS) solution slowly to prevent fluid overload (which would increase blood pressure).
- Administer IV nitroprusside (Nitropress), nicardipine (Cardene IV), or other infusion drug as prescribed (for nitroprusside, cover infusion bag to prevent drug breakdown by light); when stable, switch to oral antihypertensive drug.
- Monitor BP every 5 to 15 minutes until the diastolic pressure is below 90 and not less than 75; then monitor BP every 30 minutes to ensure that BP is not lowered too quickly.
- Observe for neurologic or cardiovascular complications, such as seizures; numbness, weakness, or tingling of extremities; dysrhythmias; or chest pain (possible indicators of target organ damage).

Provide oral and written information about the indications, dosage, times for administration, side effects, and drug interactions for antihypertensives. Stress that medication must be taken as prescribed; when all of it has been consumed, the prescription must be renewed on a continual basis. Suddenly stopping drugs such as beta blockers can result in angina (chest pain), myocardial infarction (MI), or rebound hypertension. Urge patients to report unpleasant side effects such as excessive fatigue, cough, or sexual dysfunction. In many instances, an alternative drug can be prescribed to minimize certain side effects.

Teach the patient to obtain an ambulatory blood pressure monitoring (ABPM) device for use at home so that the pressure can be checked. Evaluate the patient's and family's ability to use this device. If weight reduction is a desired outcome, suggest having a scale in the home for weight monitoring. For patients who do not want to self-monitor, are not able to self-monitor, or have "white-coat" syndrome when they go to their health care provider (causing elevated BP), continuous ABPM may be used. The monitor is worn for 24 hours or longer while patients perform their normal daily activities. Blood pressure is automatically taken every 15 to 30 minutes and recorded for review later. The advantage of this technique is that the health care provider can view the changes in BP readings throughout the 24-hour period to get a picture of a true BP value. Current evidence strongly supports 24-hour ambulatory blood pressure monitoring as a first-line procedure to determine the need for antihypertensive therapy (Verdecchia et al., 2009).

Instruct the patient about sodium restriction, weight maintenance or reduction, alcohol restriction, stress management, and exercise. If necessary, also explain about the need to stop using tobacco, especially smoking.

EVIDENCE-BASED PRACTICE

What Do Patients Need to Be Successful Self-Managers of Blood Pressure?

Schmid, A. Damush, T., Plue, L., Submanian, U., Bakas, T., & Williams, L. (2009). Current blood pressure self-management: A qualitative study. *Rehabilitation Nursing, 34*(6), 223-229.

Blood pressure self-management is well supported as a useful tool for the management of hypertension and the reduction of complications, including strokes. To assist patients to be successful self-managers, this study explored current strategies and needs for blood pressure self-management. The mixed-methods study collected data through a short questionnaire and six focused groups incorporating 16 stroke and 12 transient ischemic attack survivors. Data were analyzed to describe cohort characteristics, and comparisons were made using t-tests and chi-square test, as appropriate. Four primary blood pressure self-management themes were revealed. Participants indicated that external support from health care providers and informal caregivers helped facilitate blood pressure self-management. Health care provider support focused on enhanced patient education and communication.

Level of Evidence: 4

Although this was a small qualitative study, the researchers used several methods for data collection to answer the study question.

Commentary: Implications for Practice and Research

Nurses and other practitioners should inform patients of their actual blood pressure values during hospitalization or clinic visits, encourage patients to record their blood pressure values, and educate patients about self-management strategies. Nurses can enhance blood pressure self-management by ensuring that patients know about their target blood pressure, how to use their equipment, how and when to record their blood pressure, and what action to take based on the blood pressure results.

Health Care Resources

A home care nurse may be needed for follow-up to monitor the blood pressure. Evaluate the patient's or family's ability to obtain accurate BP measurements, and assess adherence with treatment. The American Heart Association (www.aha.org), the Red Cross, or a local pharmacy may be used for free blood

pressure checks if patients cannot buy equipment to monitor their blood pressure. Health fairs are also available in most locations.

EVALUATION: OUTCOMES

Evaluate the care of the patient with hypertension on the basis of the identified patient problems. The expected outcomes are that the patient will:

- Verbalize understanding of the plan of care, including drug therapy and any necessary lifestyle changes
- Report adverse drug effects, such as coughing, weakness, or dizziness, to the health care provider immediately
- Consistently adhere to the plan of care, including regular follow-up health care provider visits

PERIPHERAL ARTERIAL DISEASE

Peripheral vascular disease (PVD) includes disorders that change the natural flow of blood through the arteries and veins of the peripheral circulation. It affects the legs much more frequently than the arms. Generally, a diagnosis of PVD implies arterial disease (peripheral arterial disease [PAD]) rather than venous involvement. Some patients have both arterial and venous disease. The cost of the disease is very high and is expected to increase as baby boomers age and obesity in the United States continues to be a major health problem.

Pathophysiology

PAD is a result of systemic atherosclerosis. It is a chronic condition in which partial or total arterial occlusion (blockage) deprives the lower extremities of *oxygen* and nutrients. PAD in the legs is sometimes referred to as *lower extremity arterial disease (LEAD)*. Atherosclerosis leads to blockage of the arteries that supply the lower legs and feet. The tissues below the blockage (obstruction) cannot live without an adequate *oxygen* and nutrient supply.

Obstructions are classified as inflow or outflow, according to the arteries involved and their relationship to the inguinal ligament (Fig. 38-3). *Inflow* obstructions involve the distal end of the aorta and the common, internal, and external iliac arteries. They are located above the inguinal ligament. *Outflow* obstructions involve the femoral, popliteal, and tibial arteries and are below the superficial femoral artery (SFA). Gradual inflow occlusions may not cause significant tissue damage. Gradual outflow occlusions typically do.

Atherosclerosis is the most common cause of chronic arterial obstruction; therefore the risk factors for atherosclerosis apply to PAD as well. Common risk factors include hypertension, hyperlipidemia, diabetes mellitus, cigarette smoking, obesity, and familial predisposition. Advancing age also increases the risk for disease related to atherosclerosis. Patients with PAD have an increased risk for developing chronic angina, MI, or stroke and are much more likely to die within 10 years compared with those who do not have the disease.

About 10 to 12 million people in the United States have PAD, most of them older than 65 years (AHA, 2010). African Americans are affected more often than any other group, most likely because they have many risk factors such as diabetes and hypertension (AHA, 2010).

DECISION-MAKING CHALLENGE**Patient-Centered Care; Teamwork and Collaboration; Evidence-Based Practice**

A middle-aged tax attorney with a history of hypertension and smoking has an acute onset of nausea and headache. He seeks assistance from his primary care provider, who admits him immediately to the hospital. At the clinic, his heart rate is 88 beats/min, blood pressure is 220/110, and respiratory rate is 28 breaths/min.

1. Why do you think this patient was admitted on an urgent basis to the hospital?
2. What members of the health care team will be involved in this patient's care?
3. What health history and physical assessment data will you collect as the acute care nurse?
4. What type of drug therapy may be prescribed for this patient? What are your nursing responsibilities when giving these drugs?
5. What health teaching will you provide once the patient is stable? What evidence do you have to support your answer?
6. What community resources are available to assist this patient to self-manage his hypertension?

FIG. 38-3 Common locations of inflow and outflow lesions.

CHART 38-3 KEY FEATURES

Chronic Peripheral Arterial Disease

Stage I: Asymptomatic

- No claudication is present.
- Bruit or aneurysm may be present.
- Pedal pulses are decreased or absent.

Stage II: Claudication

- Muscle pain, cramping, or burning occurs with exercise and is relieved with rest.
- Symptoms are reproducible with exercise.

Stage III: Rest Pain

- Pain while resting commonly awakens the patient at night.
- Pain is described as numbness, burning, toothache-type pain.
- Pain usually occurs in the distal portion of the extremity (toes, arch, forefoot, or heel), rarely in the calf or the ankle.
- Pain is relieved by placing the extremity in a dependent position.

Stage IV: Necrosis/Gangrene

- Ulcers and blackened tissue occur on the toes, the forefoot, and the heel.
- Distinctive gangrenous odor is present.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The clinical course of chronic PAD can be divided into four stages (Chart 38-3). Patients do not experience symptoms in the early stages of disease. Most patients are not diagnosed until they develop leg pain.

Physical Assessment/Clinical Manifestations

Most patients initially seek medical attention for a classic leg pain known as **intermittent claudication** (a term derived from a word meaning “to limp”). Usually they can walk only a certain distance before a cramping, burning muscle discomfort or pain forces them to stop. The pain stops after rest. When patients resume walking, they can walk the same distance before the pain returns. Thus the pain is considered reproducible. As the disease progresses, they can walk only shorter and shorter distances before pain recurs. Ultimately, pain may occur even while at rest.

Rest pain, which may begin while the disease is still in the stage of intermittent claudication, is a numbness or burning sensation, often described as feeling like a toothache that is severe enough to awaken patients at night. It is usually located in the toes, the foot arches, the forefeet, the heels, and, rarely, in the calves or ankles. Patients can sometimes get pain relief by keeping the limb in a dependent position (below the heart). Those with rest pain often have advanced disease that may result in limb loss.

Patients with **inflow disease** have discomfort in the lower back, buttocks, or thighs. Patients with **mild** inflow disease have discomfort after walking about two blocks. This discomfort is not severe but causes them to stop walking. It is relieved with rest. Patients with **moderate** inflow disease experience pain in these areas after walking about one or two blocks. The discomfort is described as being more like pain, but it eases with rest most of the time. **Severe** inflow disease causes severe pain after walking less than one block. These patients usually have rest pain.

Patients with **outflow disease** describe burning or cramping in the calves, ankles, feet, and toes. Instep or foot discomfort indicates an obstruction below the popliteal artery. Those with **mild** outflow disease experience discomfort after walking about five blocks. This discomfort is relieved by rest. Patients with **moderate** outflow disease have pain after walking about two blocks. Intermittent rest pain may be present. Those with **severe** outflow disease usually cannot walk more than one-half block and usually experience rest pain. They may hang their feet off the bed at night for comfort and report more frequent rest pain than do those with inflow disease.

Specific findings for PAD depend on the severity of the disease. Observe for loss of hair on the lower calf, ankle, and foot; dry, scaly, dusky, pale, or mottled skin; and thickened toenails. With severe arterial disease, the extremity is cold and gray-blue (cyanotic) or darkened. Pallor may occur when the extremity is elevated. Dependent **rubor** (redness) may occur when the extremity is lowered (Fig. 38-4). Muscle atrophy can result from prolonged chronic arterial disease.

CULTURAL AWARENESS

Only severe cyanosis is evident in the skin of dark-skinned patients. To detect cyanosis, assess the skin and nail beds for a dull, lifeless color. The soles of the feet and the toenails are less pigmented and allow detection of cyanosis or duskiness in the lower extremities.

Palpate all pulses in both legs. The most sensitive and specific indicator of arterial function is the quality of the posterior tibial pulse, because the pedal pulse is not palpable in a small percentage of people. The strength of each pulse should be compared bilaterally.

FIG. 38-4 Dependent rubor in the left leg of a patient with peripheral arterial disease.

Note early signs of ulcer formation or complete ulcer formation, a complication of PAD. Arterial and venous stasis ulcers differ from diabetic ulcers ([Chart 38-4](#)). Initially, **arterial ulcers** are painful and develop on the toes (often the great toe), between the toes, or on the upper aspect of the foot. With prolonged occlusion, the toes can become gangrenous. Typically, the ulcer is small and round with a “punched out” appearance and well-defined borders. Skin lesions are discussed in further detail in [Chapter 27](#).

Imaging Assessment

Arteriography of the lower extremities may be done if stenting of the narrowed vessel is planned or to determine the exact amount of narrowing or occlusion before peripheral bypass surgery. This procedure involves injecting contrast medium into the arterial system and has serious risks including hemorrhage, thrombosis, embolus, and death. The procedure for this test is described in [Chapter 35](#).

Other Diagnostic Assessment

Noninvasive testing for arterial disease has become a more common method of diagnosis. It provides information about the arterial system with minimal risk.

Using a Doppler probe, *segmental systolic blood pressure measurements* of the lower extremities at the thigh, calf, and ankle are an inexpensive, noninvasive method of assessing PAD. Normally, blood pressure readings in the thigh and calf are higher than those in the upper extremities. With the presence of arterial disease, these pressures are lower than the brachial pressure.

With *inflow* disease, pressures taken at the thigh level indicate the severity of disease. Mild inflow disease may cause a difference of only 10 to 30 mm Hg in pressure on the affected side compared with the brachial pressure. Severe inflow disease can cause a pressure difference of more than 40 to 50 mm Hg. The ankle pressure is normally equal to or more than the brachial pressure.

To evaluate *outflow* disease, compare ankle pressure with the brachial pressure, which provides a ratio known as the **ankle-brachial index (ABI)**. The value can be derived by dividing the ankle blood pressure by the brachial blood pressure. *An ABI of less than 0.9 in either leg is diagnostic of PAD. Patients with diabetes are known to have a falsely elevated ABI.*

Doppler-derived maximal systolic acceleration is a newer technique that has demonstrated successful evaluations of peripheral arterial disease in patients with diabetes (Van Tongeren et al., 2010). *Magnetic resonance imaging* may also be used to assess blood flow in the peripheral arteries.

Exercise tolerance testing (by chemical stress test or treadmill) may give valuable information about claudication (muscle pain) without rest pain. The technician obtains resting pulse volume recordings and asks the patient to walk on a treadmill until the symptoms are reproduced. At the time of symptom onset or after about 5 minutes, the technician obtains another pulse volume recording. Normally, there may be an increased waveform with minimal, if any, drop in the ankle pressure. In patients with arterial disease, the waveforms are decreased (dampened) and there is a decrease in the ankle pressure of 40 to 60 mm Hg for 20 to 30 seconds in the affected limb. If the return to normal pressure is delayed (longer than 10 minutes), the results suggest abnormal arterial flow in the affected limb.

Plethysmography can also be performed to evaluate arterial flow in the lower extremities. The measurement provides graphs or tracings of arterial flow in the limb. If an occlusion is present, the waveforms are decreased to flattened, depending on the degree of occlusion.

INTERVENTIONS

Collaborative management of PAD may include nonsurgical interventions and/or surgery. The patient must first be assessed to determine if the altered tissue perfusion is due to arterial disease, venous disease, or both.

Nonsurgical Management

Exercise, positioning, promoting vasodilation, drug therapy, and invasive nonsurgical procedures are used to increase *arterial* flow to the affected leg(s).

Using Exercise and Positioning. *Exercise* may improve arterial blood flow to the affected leg through buildup of the collateral circulation. **Collateral circulation** provides blood to the affected area through smaller vessels that develop and compensate for the occluded vessels. Exercise is individualized for each patient, but people with severe rest pain, venous ulcers, or gangrene should not participate. Others with PAD can benefit from exercise that is started gradually and slowly increased. Instruct the patient to walk until the point of claudication, stop and rest, and then walk a little farther. Eventually, he or she can walk longer distances as collateral circulation develops. Collaborate with the health care provider and physical therapist in determining an appropriate exercise program. Exercise rehabilitation has been used to relieve symptoms but

CHART 38-4 KEY FEATURES

Lower Extremity Ulcers

FEATURE	ARTERIAL ULCERS	VENOUS ULCERS	DIABETIC ULCERS
History	Patient reports claudication after walking about 1-2 blocks Rest pain usually present Pain at ulcer site Two or three risk factors present	Chronic nonhealing ulcer No claudication or rest pain Moderate ulcer discomfort Patient reports of ankle or leg swelling	Diabetes Peripheral neuropathy No reports of claudication
Ulcer location and appearance	End of the toes Between the toes Deep Ulcer bed pale, with even edges Little granulation tissue 	Ankle area Brown pigmentation Ulcer bed pink Usually superficial, with uneven edges Granulation tissue present 	Plantar area of foot Metatarsal heads Pressure points on feet Deep Pale, with even edges Little granulation tissue 
Other assessment findings	Cool or cold foot Decreased or absent pulses Atrophy of skin Hair loss Pallor with elevation Dependent rubor Possible gangrene When acute, neurologic deficits noted	Ankle discoloration and edema Full veins when leg slightly dependent No neurologic deficit Pulses present May have scarring from previous ulcers	Pulses usually present Cool or warm foot Painless
Treatment	Treat underlying cause (surgical, revascularization) Prevent trauma and infection Patient education, stressing foot care	Long-term wound care (Unna boot, damp-to-dry dressings) Elevate extremity Patient education Prevent infection	Rule out major arterial disease Control diabetes Patient education regarding foot care Prevent infection

Photographs of venous ulcer and diabetic ulcer from Bryant, R., & Nix, D. (2007). *Acute and chronic wounds: Current management concepts* (3rd ed.). Philadelphia: Saunders.
 Photograph of arterial ulcer from Bonow, R.O., Mann, D.L., Zipes, D.P., & Libby, P. (2011). *Braunwald's heart disease: A textbook of cardiovascular medicine* (9th ed.). Philadelphia: Saunders.

requires a motivated patient. Supervised sessions are generally not reimbursed by health care insurance.

Positioning to promote circulation has been somewhat controversial. Some patients have swelling in their extremities. Because swelling prevents arterial flow, feet should be elevated. Teach them to avoid raising their legs above the heart level because extreme elevation slows arterial blood flow to the feet.

In severe cases, patients with PAD and swelling may sleep with the affected leg hanging from the bed or sit upright in a chair for comfort.

! NURSING SAFETY PRIORITY**Action Alert**

Instruct all patients with the disease to avoid crossing their legs and avoid wearing restrictive clothing (e.g., garters to hold up nylon stockings, particularly common among older women), which interfere with blood flow. Teach them the importance of inspecting their feet daily for color or other changes.

Promoting Vasodilation. Vasodilation can be achieved by providing warmth to the affected extremity and preventing long periods of exposure to cold. Encourage the patient to maintain a warm environment at home and to wear socks or insulated shoes at all times. *Caution him or her to never apply direct heat to the limb such as with the use of heating pads or extremely hot water. Sensitivity is decreased in the affected limb. Burns may result.*

Encourage patients to prevent exposure of the affected limb to the cold because cold temperatures cause vasoconstriction (decreasing of the diameter of the blood vessels) and therefore decrease arterial blood flow. They should also drink adequate fluids to prevent increased blood viscosity.

Emotional stress, caffeine, and nicotine also can cause vasoconstriction. *Emphasize that complete abstinence from smoking or chewing tobacco is the most effective method of preventing vasoconstriction.* The vasoconstrictive effects of each cigarette may last up to 1 hour after the cigarette is smoked.

 NCLEX EXAMINATION CHALLENGE**Physiological Integrity**

The nurse is caring for a client with peripheral arterial disease. Which statement made by the client concerning positioning of edematous lower extremities requires further health teaching?

- A. "I can sleep with my affected leg hanging from the bed."
- B. "I will elevate my legs above the level of my heart."
- C. "I can sit upright in a chair for comfort."
- D. "I will avoid crossing my legs at all times."

Drug Therapy. For patients with chronic PAD, prescribed drugs include hemorheologic and antiplatelet agents. Pentoxifylline (Trental) is a hemorheologic agent that increases the flexibility of red blood cells. It decreases blood viscosity by inhibiting platelet aggregation and decreasing fibrinogen and thus increases blood flow in the extremities. Many patients report limited improvement in their daily lives after taking pentoxifylline. However, those with extremely limited endurance for walking have reported improvement to the point that they can perform some activities (e.g., walk to the mailbox or dining room) that were previously impossible.

Antiplatelet agents, such as aspirin (acetylsalicylic acid, Ancasal ) and clopidogrel (Plavix), are commonly used. Aspirin 325 or 81 mg daily may be recommended for patients with chronic PAD. However, clopidogrel is better than aspirin for reducing the risk for myocardial infarction (MI), ischemic stroke, and vascular death. Patients with PAD and no contraindications to platelet therapy should receive either aspirin or clopidogrel.

Controlling hypertension can improve tissue perfusion by maintaining pressures that are adequate to perfuse the periphery but not constrict the vessels. Teach about the effect of blood pressure on the circulation, and instruct in methods of control. For example, patients taking beta blockers may have drug-related claudication or a worsening of symptoms. The health care provider closely monitors those who are receiving beta blockers.

Invasive Nonsurgical Procedures. A nonsurgical but invasive method of improving arterial flow is **percutaneous transluminal angioplasty (PTA)**. This procedure requires an arterial puncture in the patient's groin. One or more arteries are dilated with a balloon catheter advanced through a cannula, which is inserted into or above an occluded or stenosed artery. When the procedure is successful, it opens the vessel and improves arterial blood flow. Patients who are candidates for PTA must have occlusions or stenoses that are accessible to the catheter. The physician often uses this procedure for those who are poor surgical candidates, who cannot tolerate general anesthesia, or who need an amputation. Reocclusion may occur after PTA, and the procedure may be repeated. Some patients are occlusion-free for up to 3 to 5 years, whereas others may experience reocclusion within a year.

During PTA, intravascular stents (wire meshlike devices) may be inserted to ensure adequate blood flow in a stenosed vessel. Candidates for stents are patients with stenosis of the common or external iliac arteries. New stent designs are also available to effectively treat superficial femoral artery disease. These devices are cost-effective and result in shorter hospital stays and earlier recoveries.

Another arterial technique to improve blood flow to ischemic legs in people with PAD is mechanical rotational abrasive **atherectomy**. The rotator device is designed to scrape plaque from inside the artery while minimizing damage to the vessel surface.

 NURSING SAFETY PRIORITY**Critical Rescue**

The priority for nursing care following a PTA or atherectomy is to observe for bleeding at the arterial puncture site, which is usually sealed with special collagen plugs. Monitor for manifestations of impending hypovolemic shock, including a decrease in blood pressure, increased pulse rate, and decreased urinary output. Perform frequent checks of the distal pulses in both legs to ensure adequate perfusion and oxygenation.

Most patients receive anticoagulant or antiplatelet therapy, such as heparin or clopidogrel (Plavix), before and/or during the procedure. An antiplatelet drug may also be prescribed for 1 to 3 months or longer after the procedure to prevent arterial clotting.

Surgical Management

Patients with severe rest pain or claudication that interferes with the ability to work or threatens loss of a limb become surgical candidates. **Arterial revascularization** is the surgical procedure most commonly used to increase arterial blood flow in an affected limb.

Surgical procedures are classified as *inflow* or *outflow*. Inflow procedures involve bypassing arterial occlusions above the superficial femoral arteries (SFAs). Outflow procedures involve surgical bypassing of arterial occlusions at or below the SFAs. For those who have both inflow and outflow problems, the inflow procedure (for larger arteries) is done before the outflow repair.

Inflow procedures include aortoiliac, aortofemoral, and axillofemoral bypasses. Outflow procedures include femoropopliteal and femorotibial bypasses. Inflow procedures are more successful, with less chance of reocclusion or postoperative ischemia. Outflow procedures are less successful in relieving ischemic pain and are associated with a higher incidence of reocclusion.

Graft materials for bypasses are selected on an individual basis. For outflow procedures, the preferred graft material is the patient's own (**autogenous**) saphenous vein. However, some patients experience coronary artery disease and may need this vein for coronary artery bypass. When the saphenous vein is not usable, the cephalic or basilic arm veins may be used.

Grafts made of synthetic materials have also been used when autogenous veins were not available. Although synthetic grafts have achieved adequate patency in arteries above the knee, they have failed to achieve satisfactory results in infrapopliteal outflow vessels. In addition, autogenous veins are often not long enough for use in these vessels. Composite grafts constructed from multiple vein segments offer even better patency to arteries below the knee.

Preoperative Care. Preparing the patient for surgery is similar to procedures described for general or epidural anesthesia (see Chapter 16). Documentation of vital signs and peripheral pulses provides a baseline of information for

FIG. 38-5 In aortoiliac and aortofemoral bypass surgery, a midline incision into the abdominal cavity is required, with an additional incision in each groin.

comparison during the postoperative phase. Depending on the surgical procedure, the patient may have an IV line, urinary catheter, central venous catheter, and/or arterial line. To prevent postoperative infection, antibiotic therapy is typically given before the procedure.

Operative Procedures. The anesthesia provider places the patient under general, epidural, or spinal anesthesia. Epidural or spinal induction is preferred for older adults to decrease the risk for cardiopulmonary complications in this age-group. If arterial bypass is to be accomplished by autogenous grafts, the surgeon removes the veins through an incision. The blocked artery is then exposed through an incision, and the replacement vein or synthetic graft material is sutured above and below the occlusion to increase blood flow around the occlusion.

For *aortoiliac* and *aortofemoral* bypass surgery, the surgeon makes a midline incision into the abdominal cavity to expose the abdominal aorta, with additional incisions in each groin (Fig. 38-5). Graft material is tunneled from the aorta to the groin incisions, where it is sutured in place.

In an *axillofemoral* bypass (Fig. 38-6), the surgeon makes an incision beneath the clavicle and tunnels graft material subcutaneously with a catheter from the chest to the iliac crest, into a groin incision, where it is sutured in place. Neither the thoracic nor the abdominal cavity is entered. For that reason, the axillofemoral bypass is used for high-risk patients who cannot tolerate a procedure requiring abdominal surgery.

Postoperative Care. Thorough and ongoing nursing assessment for postoperative arterial revascularization patients is crucial to detect complications. Deep breathing every 1 to 2 hours and using an incentive spirometer are essential to prevent respiratory complications.

Patients who have undergone aortoiliac or aortofemoral bypass are NPO status for at least 1 day after surgery to prevent nausea and vomiting, which could increase intra-abdominal pressure. Those who have undergone bypass surgery of the lower extremities not involving the aorta or abdominal wall (femoropopliteal or femorotibial bypass)

FIG. 38-6 An axillofemoral bypass graft.

may remain NPO until the first postoperative day, when they are allowed clear liquids.

Warmth, redness, and edema of the affected extremity are often expected outcomes of surgery as a result of increased blood flow. Immediately postoperatively, the operating suite or postanesthesia care unit (PACU) nurse marks the site where the distal (dorsalis pedis or posterior tibial) pulse is best palpated or heard by Doppler ultrasonography. This information is communicated to the nursing staff on the critical care unit where the patient will be sent. “Hand-off” reporting is essential to promote safety and quality care (as required by The Joint Commission’s National Patient Safety Goals).

To promote graft patency, monitor the patient’s blood pressure and notify the surgeon if the pressure increases or decreases beyond the patient’s baseline. Hypotension may indicate hypovolemia, which can increase the risk for clotting. Range of motion of the operative leg is usually limited, with no bending of the hip and knee. Consult with the surgeon on a case-by-case basis regarding limitations of movement, including turning. Patients are usually restricted to bedrest for at least 18 to 24 hours after surgery.

Emergency **thrombectomy** (removal of the clot), which the surgeon may perform at the bedside, is the most common treatment for acute graft occlusion. Thrombectomy is associated with excellent results in prosthetic grafts. Results of thrombectomy in autogenous vein grafts are not as successful and often necessitate graft revision and even replacement.

Local intra-arterial thrombolytic (clot-dissolving) therapy with an agent such as tissue plasminogen activator (t-PA) or an infusion of a platelet inhibitor such as abciximab (ReoPro) may be used for acute graft occlusions. This therapy is provided in select settings in which health care providers are experts in its use. Other antiplatelet drugs such as the glycoprotein IIb/IIIa inhibitors *tirofiban* (Aggrastat) and

! NURSING SAFETY PRIORITY**Critical Rescue**

Graft occlusion (blockage) is a postoperative emergency that can occur within the first 24 hours after arterial revascularization. Monitor the patient for and report severe continuous and aching pain, which may be the first indicator of postoperative graft occlusion and ischemia. Many people experience a throbbing pain caused by the increased blood flow to the extremity. Because this sensation is different from ischemic pain, be sure to assess the type of pain that is experienced. Pain from occlusion may be masked by patient-controlled analgesia (PCA). Some patients have ischemic pain that is not relieved by PCA.

Monitor the patency of the graft by checking the extremity every 15 minutes for the first hour and then hourly for changes in color, temperature, and pulse intensity. Compare the operative leg with the unaffected one. If the operative leg feels cold; becomes pale, ashen, or cyanotic; or has a decreased or absent pulse, contact the surgeon immediately!

epitfibatide (*Integrilin*) may be used as alternatives. The physician considers these therapies when the surgical alternative (e.g., thrombectomy with or without graft revision or replacement) carries high morbidity or mortality rates or when surgery for this type of occlusion has traditionally yielded poor results. Closely assess the patient for manifestations of bleeding if thrombolytics are used.

Graft or wound infections can be life threatening. Use sterile technique when providing incisional care, and observe for symptoms of infection. Assess the area for induration, erythema, tenderness, warmth, edema, or drainage. Also monitor for fever and leukocytosis (increased serum white blood cell count). Notify the surgeon promptly if any of these symptoms occur.

Community-Based Care

Peripheral arterial disease (PAD) is a chronic, long-term problem with frequent complications. Patients may benefit from a case manager who can follow them across the continuum of care. The desired outcome is that the patient can be maintained in the home.

Management at home often requires an interdisciplinary team approach, including several home care visits. [Chart 38-5](#) outlines the assessment highlights for home care patients with peripheral vascular disease (PVD).

Instruct patients on methods to promote vasodilation. Teach them to avoid raising their legs above the level of the heart unless venous stasis is also present. Provide written and oral instructions on foot care and methods to prevent injury and ulcer development ([Chart 38-6](#)).

Patients who have had surgery require additional instruction on incision care (see [Chapter 18](#)). Encourage all patients to avoid smoking and to limit dietary fat intake to less than 30% of the total daily calories. Remind them to drink adequate fluids to prevent dehydration.

Patients with chronic arterial obstruction may fear recurrent occlusion or further narrowing of the artery. They often fear that they might lose a limb or become debilitated in other ways. Indeed, chronic PAD may worsen, especially in those with diabetes mellitus. Reassure them that participation in prescribed exercise, nutrition therapy, and drug therapy, along with cessation of smoking, can limit further formation of atherosclerotic plaques.

CHART 38-5 HOME CARE ASSESSMENT**The Patient with Peripheral Vascular Disease**

Assess tissue perfusion to affected extremity(ies), including:

- Distal circulation, sensation, and motion
- Presence of pain, pallor, paresthesias, pulselessness, paralysis, poikilothermy (coolness)
- Ankle-brachial index

Assess adherence to therapeutic regimen, including:

- Following foot care instructions
- Quitting smoking
- Maintaining dietary restrictions
- Participating in exercise regimen
- Avoiding exposure to cold and constrictive clothing

Assess ability to manage wound care and prevent further injury, including:

- Use of compression stockings or compression pumps as directed
- Use of various dressing materials
- Signs and symptoms to report to nurse

Assess coping ability of patient and family members.

Assess home environment, including:

- Safety hazards, especially related to falls

CHART 38-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT**Foot Care for the Patient with Peripheral Vascular Disease**

- Keep your feet clean by washing them with a mild soap in room-temperature water.
- Keep your feet dry, especially the ankles and between the toes.
- Avoid injury to your feet and ankles. Wear comfortable, well-fitting shoes. Never go without shoes.
- Keep your toenails clean and filed. Have someone cut them if you cannot see them clearly. Cut your toenails straight across.
- To prevent dry, cracked skin, apply a lubricating lotion to your feet.
- Prevent exposure to extreme heat or cold. Never use a heating pad on your feet.
- Avoid constricting garments.
- If a problem develops, see a podiatrist or physician.
- Avoid extended pressure on your feet or ankles, such as occurs when you lean against something.

Patients with arterial compromise may need assistance with ADLs if activity is limited by pain. They may need to limit or avoid stair climbing, depending on the severity of disease. Patients who have undergone surgery or need to limit activity usually need temporary help with daily activities by the family or other caregiver.

Patients who must limit activity because of PAD may benefit from the assistance of a home care aide. Those who have undergone surgery may require a home care nurse to assist with incision care. In collaboration with the case manager, arrange for home care resources before discharge.

ACUTE PERIPHERAL ARTERIAL OCCLUSION**Pathophysiology**

Although chronic peripheral arterial disease (PAD) progresses slowly, the onset of **acute arterial occlusions** may be sudden and dramatic. An **embolus** (piece of clot that travels

and lodges in a new area) is the most common cause of peripheral occlusions, although a local thrombus may be the cause. Occlusion may affect the upper extremities, but it is more common in the lower extremities. Emboli originating from the heart are the most common cause of acute arterial occlusions. Most patients with an embolic occlusion have had an acute myocardial infarction (MI) and/or atrial fibrillation within the previous weeks.

PATIENT-CENTERED COLLABORATIVE CARE

Patients with an acute arterial occlusion describe severe pain below the level of the occlusion that occurs even at rest. The affected extremity is cool or cold, pulseless, and mottled. Small areas on the toes may be blackened or gangrenous. *Those with acute arterial insufficiency often present with the “six P’s” of ischemia:*

- Pain
- Pallor
- Pulselessness
- Paresthesia
- Paralysis
- Poikilothermy (coolness)

The health care provider must initiate treatment promptly to avoid permanent damage or loss of an extremity. Anticoagulant therapy with unfractionated heparin (UFH, Hepalean ) is usually the first intervention to prevent further clot formation. A bolus of up to 10,000 units may be prescribed. The patient may undergo angiography.

A surgical *thrombectomy* or *embolectomy* with local anesthesia may be performed to remove the occlusion. The physician makes a small incision, which is followed by an **arteriotomy** (a surgical opening into an artery). A catheter is inserted into the artery to retrieve the embolus. It may be necessary to close the artery with a synthetic or autologous (patient’s own blood vessel) patch graft.

! NURSING SAFETY PRIORITY

Critical Rescue

After an arterial thrombectomy, observe the affected extremity for improvement in color, temperature, and pulse every hour for the first 24 hours or according to the postoperative surgical protocol. Monitor patients for manifestations of new thrombi or emboli, especially pulmonary emboli (PE). Chest pain, dyspnea, and acute confusion (older adults) typically occur in patients with PE. Notify the health care provider or Rapid Response Team immediately if these symptoms occur.

Pain should significantly diminish after the surgical procedure, although mild incisional pain remains. Watch closely for complications caused by reperfusion of the artery after thrombectomy or embolectomy, which include spasms and swelling of the skeletal muscles. Swelling of the skeletal muscles can result in compartment syndrome.

Compartment syndrome occurs when tissue pressure within a confined body space becomes elevated and restricts blood flow. The resulting ischemia can lead to tissue damage and eventually tissue death. Assess the motor and sensory function of the affected extremity. Monitor for increasing

pain, swelling, and tenseness. Report any of these symptoms to the health care provider immediately. **Fasciotomy** (surgical opening into the tissues) may be necessary to prevent further injury and save the limb.

The use of *systemic thrombolytic therapy* for acute arterial occlusions has been disappointing because bleeding complications often outweigh the benefits obtained. Local intra-arterial thrombolytic therapy with alteplase (Activase) or t-PA and the use of platelet inhibitors, such as abciximab (ReoPro), have emerged as alternatives to surgical treatment in selected settings.

! NURSING SAFETY PRIORITY

Drug Alert

When *thrombolytics* are given, assess for signs of bleeding, bruising, or hematoma. For patients receiving any *platelet inhibitor*, monitor platelet counts for the first 3, 6, and 12 hours after the start of the infusion. If the platelet count decreases to below 100,000/mm³, the abciximab infusion needs to be readjusted or discontinued. If any of these complications occur, notify the physician or Rapid Response Team immediately.

ANEURYSMS OF CENTRAL ARTERIES

Pathophysiology

An **aneurysm** is a permanent localized dilation of an artery, which enlarges the artery to at least two times its normal diameter. It may be described as *fusiform* (a diffuse dilation affecting the entire circumference of the artery) or *saccular* (an outpouching affecting only a distinct portion of the artery). Aneurysms may also be described as *true* or *false*. In true aneurysms, the arterial wall is weakened by congenital or acquired problems. False aneurysms occur as a result of vessel injury or trauma to all three layers of the arterial wall. *Dissecting aneurysms*, such as *aortic dissections* (see the later discussion on p. 796) differ from aneurysms in that they are formed when blood accumulates in the wall of an artery.

Aneurysms tend to occur at specific anatomic sites (Fig. 38-7), most commonly in the abdominal aorta. They often occur at a point where the artery is not supported by skeletal muscles or on the lines of curves or flexion in the arterial tree.

An aneurysm forms when the middle layer (media) of the artery is weakened, producing a stretching effect in the inner layer (intima) and outer layers of the artery. As the artery widens, tension in the wall increases and further widening occurs, thus enlarging the aneurysm and increasing the risk for arterial rupture. Elevated blood pressure can also increase the rate of aneurysmal enlargement and risk for early rupture. When *dissecting aneurysms* occur, the aneurysm enlarges, blood is lost, and blood flow to organs is diminished.

Abdominal aortic aneurysms (AAAs) account for most aneurysms, are commonly asymptomatic, and frequently rupture. Most of these are located between the renal arteries and the aortic bifurcation (dividing area).

Thoracic aortic aneurysms (TAAs) are not quite as common and are frequently misdiagnosed. They are typically discovered when advanced imaging is used to assess other conditions. TAAs commonly develop between the origin of the left

FIG. 38-7 Common anatomic sites of arterial aneurysms.

subclavian artery and the diaphragm. They are located in the descending, ascending, and transverse sections of the aorta. They can also occur in the aortic arch and are very difficult to manage surgically.

Aneurysms can cause symptoms by exerting pressure on surrounding structures or by rupturing. *Rupture is the most frequent complication and is life threatening because abrupt and massive hemorrhagic shock results.* Thrombi within the wall of an aneurysm can also be the source of emboli in distal arteries below the aneurysm.

Atherosclerosis is the most common cause of aneurysms, with hypertension, hyperlipidemia, and cigarette smoking being contributing factors. Age, gender, and family history also play a role (Forsdahl et al., 2009). Syphilis (a sexually transmitted disease), Marfan syndrome (a connective tissue disease), and Ehlers-Danlos syndrome (a rare genetic disorder) are other causes of AAAs. Chronic inflammation (aortitis) and blunt trauma, usually from motor vehicle crashes, can cause aneurysms in the descending thoracic aorta (Hiratzka et al., 2010).

Abdominal aortic aneurysm rupture remains a significant cause of death in the United States. Death occurs more often in male patients and those older than 65 years (Forsdahl et al., 2009). Thoracic aortic aneurysms also occur most often in

older adults and have a high mortality rate even with surgical intervention.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Most patients with abdominal or thoracic aneurysms are asymptomatic when their aneurysms are first discovered by routine examination or during an imaging study performed for another reason. However, a few patients do have symptoms that bring them to their health care provider or the emergency department.

Physical Assessment/Clinical Manifestations

Assess patients with a known or suspected *abdominal aortic aneurysm (AAA)* for abdominal, flank, or back pain. Pain is usually described as steady with a gnawing quality, unaffected by movement, and lasting for hours or days.

A pulsation in the upper abdomen slightly to the left of the midline between the xiphoid process and the umbilicus may be present. A detectable aneurysm is at least 5 cm in diameter. *Auscultate for a bruit over the mass, but avoid palpating the mass because it may be tender and there is risk for rupture!* If expansion and impending rupture of an AAA are suspected, assess for severe pain of sudden onset in the back or lower abdomen, which may radiate to the groin, buttocks, or legs.

Patients with a rupturing AAA are critically ill and in hemorrhagic (hypovolemic) shock. Signs include hypotension, diaphoresis, decreased level of consciousness, oliguria (scant urine output), loss of pulses distal to the rupture, and dysrhythmias. Retroperitoneal hemorrhage is manifested by hematomas in the flanks (lower back). Rupture into the abdominal cavity causes abdominal distention.

When a *thoracic aortic aneurysm* is suspected, assess for back pain and manifestations of compression of the aneurysm on adjacent structures. Signs include shortness of breath, hoarseness, and difficulty swallowing. TAAs are not often detected by physical assessment, but occasionally a mass may be visible above the suprasternal notch. Assess the patient with suspected rupture of a thoracic aneurysm for sudden and excruciating back or chest pain. Hypovolemic shock also occurs with TAA.

Imaging Assessment

Computed tomography (CT) scanning is the standard tool for assessing the size and location of an abdominal or thoracic aneurysm. An abdominal x-ray or a lateral x-ray of the spine often shows an AAA. The “eggshell” appearance of the aneurysm supports the diagnosis. *Ultrasonography* is a noninvasive technique that provides an accurate diagnosis, as well as information about the size and location of an AAA. A thoracic aneurysm can be diagnosed by chest x-ray. *Aortic arteriography* is usually performed for patients who are to undergo surgical repair of a thoracic aneurysm.

INTERVENTIONS

The size of the aneurysm and the presence of symptoms determine patient management. The nurse’s role is to perform frequent patient assessments, including blood pressure, pulse, and peripheral circulation checks.

Nonsurgical Management

The desired outcome of nonsurgical management is to monitor the growth of the aneurysm and maintain the blood pressure at a normal level to decrease the risk for rupture. Patients with hypertension are treated with antihypertensive drugs to decrease the rate of enlargement and the risk for early rupture.

For those with small or asymptomatic aneurysms, frequent ultrasound or CT scans are necessary to monitor the growth of the aneurysm. Emphasize the importance of following through with scheduled tests to monitor the growth. Also explain the clinical manifestations of aneurysms that need to be promptly reported.

Surgical Management

Surgical management of an aneurysm may be an elective or an emergency procedure. *For patients with a rupturing abdominal aortic or a thoracic aneurysm, emergency surgery is performed.* Patients with TAAs measuring 2.8 inches (7 cm) or more in diameter and those with smaller aneurysms that are producing symptoms are advised to have elective surgery. Those with smaller aneurysms that are not causing symptoms are treated nonsurgically until symptoms occur or the aneurysm enlarges.

The most common surgical procedure for AAA has traditionally been a resection or repair (**aneurysmectomy**). However, the mortality rate for elective resection is high and markedly increases for emergency surgery.

Endovascular stent grafts have improved mortality rates and shortened the hospital stay for select patients who need AAA repair. Stents (wirelike devices) are inserted percutaneously (through the skin), avoiding abdominal incisions and therefore decreasing the risk for a prolonged postoperative recovery. Postoperative care is similar to care required after an arteriogram (angiogram).

Abdominal Aortic Aneurysm Resection. In an AAA resection, the physician excises (cuts out) the aneurysm from the abdominal aorta to prevent or repair the rupture. The desired outcome is to secure stable aortic integrity and tissue perfusion throughout the body.

Preoperative Care. Preoperative care is similar to that for patients undergoing any surgery with general anesthesia (see Chapter 16). A bowel preparation and emphasis on coughing and deep breathing are very important. Because significant blood loss may occur during AAA resection, patients planning elective surgery may be advised to bank their blood for autologous (using patient's own blood) transfusions during and after surgery.

Assess all peripheral pulses to serve as a baseline for comparison postoperatively. Use a marker to note where the pulse is palpated or heard by Doppler ultrasonography to facilitate locating the pulse postoperatively.

Patients with ruptured aneurysms are brought to the operating suite directly from the emergency department. Preoperative care of patients with ruptured aneurysms involves administration of large volumes of IV fluids to maintain organ tissue perfusion.

Operative Procedures. The surgeon makes a midline abdominal incision from the xyphoid process to the symphysis pubis or a wide transverse incision from flank to flank to expose the aneurysm. Clamps are applied just above and just

below the aneurysm, the aneurysm is excised, and a synthetic graft is sutured in an end-to-end fashion.

Postoperative Care. Immediately after surgery, the patient is typically admitted to a critical care unit for 24 hours, depending on his or her age and condition. Limit elevation of the head of the bed to 45 degrees or less to avoid flexion of the graft. In addition to providing the usual care discussed in Chapter 18, assess for and assist in prevention of the postoperative complications that can occur after an AAA repair. Complications include:

- Myocardial infarction
- Graft occlusion or rupture causing hemorrhage
- Hypovolemia and/or renal failure
- Respiratory distress
- Paralytic ileus

During the immediate postoperative period, the patient's blood pressure is monitored with an arterial catheter. Continuous cardiac monitoring is used to detect any dysrhythmias. Hemodynamic monitoring is used to detect low cardiac output and other findings consistent with an acute *myocardial infarction*. Other signs of myocardial infarction include chest pain, shortness of breath, diaphoresis (excessive sweating), anxiety, and restlessness.

! NURSING SAFETY PRIORITY

Action Alert

A major priority for nursing care after an AAA surgical repair is to assess for signs of graft occlusion or rupture. Assess vital signs and circulation every 15 minutes for the first hour and then hourly, with assessment of pulses distal to the graft site (including the posterior tibial and dorsalis pedis pulses). Report signs of *graft occlusion or rupture*, including:

- Changes in pulses
- Cool to cold extremities below the graft
- White or blue extremities or flanks
- Severe pain
- Abdominal distention
- Decreased urine output

Hypovolemia and acute renal failure may occur because of blood loss during surgery or before if rupture occurred. Assess urine output hourly. If urine output is less than 50 mL/hr, notify the surgeon immediately. Although advances in surgical technique have decreased the risk for renal failure after clamping during surgery, renal failure may occur. Renal failure caused by acute tubular necrosis (ATN) is more common after emergency surgery. In addition to monitoring urine output, in collaboration with the physician, monitor serum creatinine and blood urea nitrogen (BUN) levels daily.

Assess respiratory rate and depth every hour and auscultate breath sounds every 4 hours to monitor for *respiratory complications*. The patient may be mechanically ventilated and should be extubated as soon as he or she is stable. While the patient is intubated, turn and suction him or her as needed. Administer opioids for pain as prescribed. After extubation, assist the patient to a bedside chair within 24 hours. Early mobility decreases the risk for atelectasis and deep vein thrombosis. Teach him or her to use firm abdominal support of the incision with a pillow or bath blanket during coughing exercises.

Paralytic ileus after AAA repair is expected for 2 to 3 days. Patients usually have a nasogastric tube set to low suction until they begin to pass flatus. Listen for bowel sounds and assess for flatus every 8 hours. Report when bowel sounds return and any flatus to the physician. Some surgeons begin to introduce fluids or soft food to stimulate peristalsis. Prolonged absence of flatus and presence of abdominal distention may indicate a paralytic ileus or a bowel infarction.

NLCEX EXAMINATION CHALLENGE

Physiological Integrity

A client who had an abdominal aneurysm repair yesterday has a urinary output of 25 mL/hr and a blood urea nitrogen (BUN) of 68 mg/dL. What action should the nurse take first?

- A. Call the surgeon immediately.
- B. Assess the client's vital signs.
- C. Increase the intravenous fluid rate.
- D. Continue to monitor the client.

Thoracic Aortic Aneurysm Repair. Repair of thoracic aneurysms is tailored to each patient. The procedure depends on the type and location of the aneurysm. Total cardiopulmonary bypass (CPB) is necessary for excision of aneurysms in the ascending aorta, and partial bypass is often used during excision of aneurysms in the descending aorta.

The care of the patient undergoing thoracic aneurysm resection is similar to that for the patient having thoracic surgery. [Chapter 34](#) describes thoracic surgery in detail.

The surgeon uses either a thoracotomy or a median sternotomy approach to enter the thoracic cavity. A synthetic graft or prosthesis is sewn onto the aorta in place of the excised TAA. Saccular aneurysms, which have an outpouching from a distinct portion of the arterial wall, can sometimes be removed without aortic resection. Newer procedures do not remove the aneurysm. Instead, the surgeon cuts into the aneurysm and inserts a graft. The walls of the aneurysm are wrapped around the graft for stability.

Assess for and help prevent postoperative complications that can occur after a thoracic aneurysm repair. Complications include:

- Hemorrhage
- Ischemic colitis
- Cerebral and spinal cord ischemia (causing paraplegia)
- Respiratory distress
- Infection
- Cardiac dysrhythmias

NURSING SAFETY PRIORITY

Critical Rescue

After TAA repair, assess vital signs at least hourly, reporting any signs of hemorrhage (e.g., a decrease in blood pressure, an increase in pulse rate, rapid respirations, diaphoresis) to the surgeon or Rapid Response Team immediately. Assess for bleeding or separation at the graft site by noting significant increases in drainage from the chest tubes.

Accidental interruption of the blood supply to the spinal cord during thoracic aneurysm repair can result in paraplegia. Assess the patient hourly for sensation and motion in all extremities, and report changes immediately!

After TAA repair, patients are especially likely to develop *respiratory distress* from atelectasis or pneumonia. This problem occurs as a result of both CPB and incisional discomfort. Both atelectasis and pneumonia may cause shallow breathing and poor cough effort. These patients are often mechanically ventilated at least overnight after surgery.

Health care–acquired infection is a major concern for any vascular surgery. Be sure to wash your hands and use strict sterile technique for incisional care. The patient usually receives IV antibiotics within an hour before surgery. The Joint Commission (TJC) and other groups have placed a major emphasis on preventing infection while patients are in the hospital (National Patient Safety Goals).

Assess all patients recovering from TAA repair for cardiac *dysrhythmias*. The stress of the thoracic surgery, added to the increased incidence of arteriosclerosis in this group, may predispose patients to a myocardial infarction, cardiac dysrhythmias, or heart failure.

Endovascular Repair of Abdominal Aortic Aneurysms.

The repair of AAAs with **endovascular stent grafts** is an alternative for some patients. Those selected for endovascular repair of AAAs are generally at high risk for major abdominal surgery. Some patients may be referred for endovascular repair before the aneurysm reaches the recommended diameter for elective surgery.

Different designs of endovascular stent grafts are used, depending on the anatomic involvement of the aneurysm. The stent graft is flexible with either Dacron or polytetrafluoroethylene (PTFE) material. It is inserted through a skin incision into the femoral artery by way of a catheter-based system. The catheter is advanced to a level above the aneurysm away from the renal arteries. The graft is released from the catheter, and the stent graft is placed with a series of hooks. This procedure is done in collaboration with the vascular surgeon, interventional radiologist, operating suite team, and, at some centers, vascular medicine physician.

Complications for stent repair include:

- Conversion to open surgical repair
- Bleeding
- Aneurysm rupture
- Peripheral embolization
- Misplacement of the stent graft

The endovascular repair of AAAs has decreased the length of hospital stay for patients requiring repair of abdominal aneurysms. However, the patient needs to be closely monitored, in the hospital and at home, for the development of complications after the procedure. Expert nursing care is required to allow for early identification of problems, and complications require timely surgical intervention. In addition, coordination and collaboration with the health care team are required for discharge planning and follow-up care for patients at home.

Community-Based Care

Most patients are discharged to home after aneurysm repair. However, in the absence of family or other support systems, the postoperative patient may be discharged to a transitional care or long-term care facility for rehabilitation.

If discharged to home, the patient must follow instructions regarding activity level and incisional care. Because stair climbing may be restricted initially, he or she may

need a bedside commode if the bathroom is inaccessible. Teach the patient who has undergone surgical repair about activity restrictions, wound care, and pain management. Patients may not perform activities that involve lifting heavy objects (usually more than 15 to 20 pounds [6.8 to 9.1 kg]) for 6 to 12 weeks postoperatively. Advise them to use caution for activities that involve pulling, pushing, or straining. Those who usually engage in vigorous activities should discuss them with their health care provider. Most patients are restricted from driving a car for several weeks after discharge.

For patients who have not undergone surgical aneurysm repair, the teaching plan emphasizes the importance of compliance with the schedule of frequent CT scanning to monitor the size of the aneurysm.

! NURSING SAFETY PRIORITY

Action Alert

Teach patients receiving treatment for hypertension about the importance of continuing to take prescribed drugs. Instruct them about the signs and symptoms that must promptly be reported to the health care provider, which include:

- Abdominal fullness or pain or back pain
- Chest or back pain
- Shortness of breath
- Difficulty swallowing or hoarseness

In collaboration with the case manager or social worker, assess the availability of transportation to and from appointments for patients needing CT monitoring. Those who have undergone surgery may require the services of a home care nurse for initial assistance with dressing changes. A home care aide may be needed to assist with ADLs, depending on the patient's support system.

ANEURYSMS OF THE PERIPHERAL ARTERIES

Although femoral and popliteal aneurysms are not common, they are often associated with an aneurysm in another location of the arterial tree (see Fig. 38-7). To detect a popliteal aneurysm, assess for a pulsating mass in the popliteal space. To detect a femoral aneurysm, observe a pulsatile mass over the femoral artery. Evaluate both extremities because more than one femoral or popliteal aneurysm may be present.

The patient may have symptoms of limb ischemia (decreased blood flow), including diminished or absent pulses, cool to cold skin, and pain. Pain also may be present if an adjacent nerve is compressed. The recommended treatment for either type of aneurysm, regardless of the size, is surgery because of the risk for thromboembolic complications.

To treat a femoral aneurysm, the surgeon removes the aneurysm and restores circulation using a synthetic graft or an autogenous saphenous vein graft. Most surgeons prefer to bypass rather than resect a popliteal aneurysm.

After surgery, monitor for lower limb ischemia. Palpate pulses below the graft to assess graft patency. Often, Doppler ultrasonography is necessary to assess blood flow when pulses are not palpable. *Report sudden development of pain or discoloration of the extremity immediately to the physician because it may indicate graft occlusion.*

AORTIC DISSECTION

Pathophysiology

Aortic dissection has traditionally been referred to as a *dissecting aneurysm*. However, because this condition is more accurately described as a *dissecting hematoma*, the term *aortic dissection* is more commonly used. Aortic dissection is not common but is a life-threatening problem.

Aortic dissection is thought to be caused by a sudden tear in the aortic intima, opening the way for blood to enter the aortic wall. Degeneration of the aortic media may be the primary cause for this condition, with hypertension being an important contributing factor. It is often associated with connective tissue disorders such as Marfan syndrome. It occurs also in middle-aged and older people, peaking in adults in their 50s and 60s. Men are more commonly affected than women (Hiratzka et al., 2010).

The circulation of any major artery arising from the aorta can be impaired in patients with aortic dissection; therefore this condition is highly lethal and represents an emergency situation. Although the ascending aorta and descending thoracic aorta are the most common sites, dissections can also occur in the abdominal aorta and other arteries.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The most common symptom is pain. It is described as “tearing,” “ripping,” and “stabbing” and tends to move from its point of origin. Depending on the site of dissection, the patient may feel pain in the anterior chest, back, neck, throat, jaw, or teeth.

Diaphoresis (excessive sweating), nausea, vomiting, faintness, and apprehension are also common. Blood pressure is usually elevated unless complications such as cardiac tamponade or rupture have occurred. In these cases, the patient becomes rapidly hypotensive. A decrease or absence of peripheral pulses is common, as is aortic regurgitation, which is characterized by a musical murmur best heard along the right sternal border. Neurologic deficits such as an altered level of consciousness, paraparesis, and strokes also can occur.

Chest x-ray, computed tomography (CT), magnetic resonance imaging (MRI), and aortic angiography may be used to confirm the diagnosis. However, MRI scanning is very time-consuming and may not be the test of choice. Transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE) may be performed at the bedside for patients who cannot be moved (Braverman, 2010).

INTERVENTIONS

The expected outcomes for emergency care for a patient with an aortic dissection are:

- Elimination of pain
- Reduction of systolic blood pressure to 100 to 120 mm Hg
- Decrease in the velocity of left ventricular ejection

The physician prescribes IV sodium nitroprusside (Nitropress, Nipride) or fenoldopam (Corlopam) by continuous drip initially to lower the blood pressure. If this regimen is

not effective, nicardipine hydrochloride (Cardene) may be used.

Subsequent treatment depends on the location of the dissection. Patients receive continued medical treatment for uncomplicated distal dissections and surgical treatment for proximal dissections. For those receiving long-term medical treatment, the systolic blood pressure must be maintained at or below 130 to 140 mm Hg. Beta blockers (e.g., propranolol) and calcium channel antagonists (amlodipine) are prescribed to assist with blood pressure maintenance.

Patients having surgical intervention for a proximal dissection always require cardiopulmonary bypass (CPB) (see Chapter 40). The surgeon removes the intimal tear and sutures edges of the dissected aorta. Usually, a synthetic graft is used.

BUERGER'S DISEASE

Pathophysiology

Buerger's disease (thromboangiitis obliterans) is an uncommon occlusive disease of the arteries and veins in the distal portion of the upper and lower extremities. The disease often extends into the tissues around the vessels, resulting in fibrosis and scarring that bind the artery, vein, and nerve firmly together. Larger arteries such as the femoral and brachial become involved in the late stages of the disease. The veins are less commonly involved.

The cause of Buerger's disease is unknown although there is a strong association with tobacco smoking and is typically identified in young adult men who smoke. Cessation of cigarette smoking usually arrests the disease process. Continued smoking causes occlusion in the more proximal vessels. A familial or genetic predisposition and autoimmune etiologic factors are also possible.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The first clinical manifestation of Buerger's disease is usually **claudication** (muscle pain caused by an inadequate blood supply) of the arch of the foot. Intermittent claudication may occur in the lower extremities. The pain may be ischemic, occurring in the digits while the patient is at rest. Often there is an aching pain that is more severe at night. Intermittent shocklike pain can be the result of ischemic neuropathy. Patients often have increased sensitivity to cold and report coldness and numbness. On physical examination, pulses are often diminished in the distal extremities and the extremities are cool and red or cyanotic in the dependent position.

A diagnosis of Buerger's disease is based on a physical finding of peripheral ischemia. Ulcerations and gangrene may be seen in the digits. The ulcerations are usually sharply demarcated. The gangrenous lesion can be small or can affect the entire digit.

Arteriograms can be useful in delineating the degree of disease in the arteries. Commonly, arteriography reveals multiple segmental occlusions in the smaller arteries of the forearm, hand, leg, and foot. Plethysmographic studies of the fingers or toes may be diagnostic of the disease in the early

stages. These studies can also be useful in following the progression of the disease in more proximal arteries (see Chapter 35 for discussion of these tests).

INTERVENTIONS

Nursing interventions are directed toward:

- Preventing the progression of the disease
- Avoiding vasoconstriction
- Promoting vasodilation
- Relieving pain
- Managing ulceration and gangrene

To prevent the progression of Buerger's disease, complete abstinence from tobacco in all forms is essential. Teach the patient to avoid extreme cold or prolonged exposure to cold to prevent vasoconstriction. Instruct him or her about drugs that may be used for vasodilation (e.g., nifedipine [Procardia]). The collaborative care for Buerger's disease is similar to that for peripheral arterial disease (PAD) (see the discussion of Interventions on p. 787 in the Peripheral Arterial Disease section).

SUBCLAVIAN STEAL

Subclavian steal occurs in the upper extremities as a result of a subclavian artery occlusion or stenosis. The result is altered blood flow and ischemia in the arm. Subclavian steal can occur in people at any age but is more common in those with risk factors for atherosclerosis. Symptoms include tiredness in the arm with exertion, paresthesias, dizziness, and exercise-induced pain in the forearms when the arms are elevated.

Physical assessment usually reveals a significant difference in the blood pressures between the arms. A difference greater than 20 mm Hg is considered significant. Another important finding is a subclavian bruit, which can occur on the affected side. The subclavian pulse may be decreased on the occluded side compared with the opposite side. In severe cases, the affected arm may also be discolored or cyanotic.

Surgery is the recommended intervention for cyanosis or pain. One of three procedures may be used: endarterectomy of the subclavian artery, carotid-subclavian bypass, or dilation of the subclavian artery with placement of a vascular stent.

Postoperative nursing care of the patient includes monitoring of the arterial flow in the affected arm. Check brachial and radial pulses frequently, and observe for ischemic changes. Observe the arm for edema, redness, or any other signs.

THORACIC OUTLET SYNDROME

Thoracic outlet syndrome is a compression of the subclavian artery at the thoracic outlet by anatomic structures such as a rib or muscle. The arterial wall may be damaged, producing thrombosis or embolization to distal arteries of the arms. The three common sites of compression in the thoracic outlet are:

- The costoclavicular space (most common)
- The interscalene triangle
- Between the coracoid process of the scapula and the pectoralis minor tendon

Thoracic outlet syndrome is more common in women and in those whose occupations require holding their arms up or leaning over, such as baseball players, golfers, and swimmers. It is also seen in people who have had trauma (e.g., whiplash)

or clavicular fracture. Patients generally report neck, shoulder, and arm pain that may be intermittent. They may also have numbness and moderate edema of the extremity. The pain and numbness are worse when the arm is placed in certain positions such as over the head or out to the side. Some patients may have overdeveloped neck and shoulder muscles, and the affected arm may appear cyanotic.

Collaborative care includes physical therapy, exercises, and avoiding aggravating positions such as elevating the arms. Surgical management involves resection of the anatomic structure that is compressing the artery. Surgery is performed only if a patient has severe pain, has lost hand function, or is responding poorly to conservative treatment.

RAYNAUD'S PHENOMENON/DISEASE

Pathophysiology

Raynaud's phenomenon is caused by vasospasm of the arterioles and arteries of the upper and lower extremities, usually unilaterally. *Raynaud's disease* occurs bilaterally. The two terms are sometimes used interchangeably. Although they are related, there are some differences. Raynaud's phenomenon usually occurs in people older than 30 years. Raynaud's disease can occur between the ages of 17 and 50 years. Raynaud's phenomenon can occur in either gender, Raynaud's disease is more common in women.

The pathophysiology is the same for both entities. The etiology is unknown. Patients often have an associated systemic connective tissue disease such as systemic lupus erythematosus or progressive systemic sclerosis (see [Chapter 20](#)).

As a result of vasospasm, the superficial skin vessels are constricted and blanching of the extremity occurs, followed by cyanosis. When the vasospasm is relieved, the tissue becomes reddened or hyperemic ([Fig. 38-8](#)). The patient's extremities are numb and cold, and he or she may report pain and swelling. Ulcers may also be present. These attacks are intermittent and can be aggravated by cold or stress. In severe cases, the attack lasts longer and gangrene of the digits can occur.

PATIENT-CENTERED COLLABORATIVE CARE

Management involves relieving or preventing the vasoconstriction by drug therapy. Commonly prescribed drugs are nifedipine (Procardia), cycloandelate (Cyclospasmol), and phenoxybenzamine (Dibenzylamine). These vasodilating agents may help relieve the symptoms, but they can cause uncomfortable side effects such as facial flushing, headaches, hypotension, and dizziness.

For severe symptoms that are not reduced by drugs, a lumbar sympathectomy may be performed. The surgeon cuts the sympathetic nerve fibers that cause vasoconstriction of blood vessels in the legs. This method is effective for foot symptoms. For the upper extremities, a similar procedure—sympathetic ganglionectomy—may provide symptom relief. The long-term effectiveness of these treatments is questionable.

Patient education is important in prevention of complications. Explain methods to prevent vasoconstriction, such as minimizing exposure to cold, reducing caffeine intake,

FIG. 38-8 Color changes of Raynaud's phenomenon.

smoking cessation (if the patient smokes), and decreasing stress. *Teach the patient to wear warm clothes, socks, and gloves when exposed to cool or cold temperatures. He or she should keep the home at a comfortably warm temperature and wear gloves to the grocery store.* Help the patient identify stressors, and provide suggestions for reducing them. (See [Chapter 20](#) for further discussion of Raynaud's phenomenon as it relates to connective tissue disease.)

PERIPHERAL VENOUS DISEASE

To function properly, veins must be patent (open) with competent valves. Vein function also requires the assistance of the surrounding muscle beds to help pump blood toward the heart. If one or more veins are not operating properly, they become distended and clinical manifestations occur.

Three health problems alter the blood flow in veins:

- Thrombus formation (*venous thrombosis*) can lead to pulmonary embolism (PE), a life-threatening complication. **Venous thromboembolism (VTE)** is the current term that includes both deep vein thrombosis and PE.
- Defective valves lead to *venous insufficiency* and *varicose veins*, which are not life threatening but are problematic.
- Skeletal muscles do not contract to help pump blood in the veins. This problem can occur when weight-bearing is limited or muscle tone decreases.

VENOUS THROMBOEMBOLISM

Pathophysiology

Venous thromboembolism (VTE) is one of health care's greatest challenges and includes both thrombus and embolus complications. A **thrombus** (also called a *thrombosis*) is a blood clot believed to result from an endothelial injury, venous stasis, or hypercoagulability. The thrombosis may be specifically attributable to one element, or it may involve all three elements. It is often associated with an inflammatory process. When a thrombus develops, inflammation occurs around the clot, thickening the vein wall and consequently possibly leading to embolization (the formation of an **embolus**). Pulmonary embolism (PE) is the most common type of embolization and is discussed in detail in [Chapter 34](#).

Thrombophlebitis refers to a thrombus that is associated with inflammation. **Phlebothrombosis** is a thrombus without inflammation. Thrombophlebitis can occur in superficial veins. However, it most frequently occurs in the deep veins of the lower extremities.

Deep vein thrombophlebitis, commonly referred to as **deep vein thrombosis (DVT)**, is the most common type of thrombophlebitis. Deep vein thrombophlebitis (thrombosis) is more serious than superficial thrombophlebitis because it presents a greater risk for PE. In PE, a dislodged blood clot travels to the pulmonary artery. DVT develops most often in the legs but can occur also in the upper arms as a result of increased use of central venous devices.

Thrombus formation has been associated with stasis of blood flow, endothelial injury, and/or hypercoagulability, known as **Virchow's triad**. The precise cause of these events remains unknown; however, a few predisposing factors have been identified.

The highest incidence of clot formation occurs in patients who have undergone hip surgery, total knee replacement, or open prostate surgery. Other conditions that seem to promote thrombus formation are ulcerative colitis, heart failure, cancer, oral contraceptives, and immobility. Complications of immobility occur during prolonged bedrest such as when a patient is confined to bed for an extensive illness. People who sit for long periods (e.g., on an airplane) are also at risk. **Phlebitis** (vein inflammation) associated with invasive procedures such as IV therapy can predispose patients to thrombosis.

Millions of people in the United States are affected by deep vein thrombosis each year, and many die from pulmonary embolism. The largest number of deaths occurs in older adults. African Americans have a higher rate of death resulting from PE because of predisposing risk factors and coexisting diseases, such as cancer, chronic kidney disease, and cardiac failure.

Health Promotion and Maintenance

In the *community*, if a person has a history of any type of VTE, these precautions should be taken:

- Avoid oral contraceptives.
- Drink adequate fluids to avoid dehydration.
- Exercise legs during long periods of bedrest or sitting.

In the *inpatient setting*, interventions to prevent any type of VTE include:

- Patient education
- Leg exercises

- Early ambulation
- Adequate hydration
- Graduated compression stockings
- Intermittent pneumatic compression, such as sequential compression devices (SCDs)
- Venous plexus foot pump

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

People with DVT may have symptoms or may be asymptomatic. *The classic signs and symptoms of DVT are calf or groin tenderness and pain and sudden onset of unilateral swelling of the leg.* Pain in the calf on dorsiflexion of the foot (positive Homans' sign) appears in only a small percentage of patients with DVT, and false-positive findings are common. *Therefore checking a Homans' sign is not advised!* Examine the area described as painful, comparing this site with the other limb. Gently palpate the site, observing for **induration** (hardening) along the blood vessel and for warmth and edema. Redness may also be present ([Fig. 38-9](#)).

Localized edema in one extremity may suggest DVT. Some experts suggest to measure and compare right and left calf and thigh circumferences for changes over time as an indicator of DVT or venous insufficiency. However, serial leg measurements are not the most reliable indicator.

Although diagnostic tests are available, physical examination findings are often adequate for diagnosis. If a definitive diagnosis is lacking from physical assessment findings alone, diagnostic tests may be performed.

The preferred diagnostic test for DVT is *venous duplex ultrasonography*, a noninvasive ultrasound that assesses the flow of blood through the veins of the arms and legs. *Doppler flow studies* may also be useful in the diagnosis, but they are more sensitive in detecting proximal rather than distal DVT. Normal venous circulation creates audible signals, whereas thrombosed veins produce little or no sound. The accuracy of the scanning depends on the technical skill of the health care professional performing the test. If the test is negative

FIG. 38-9 Deep vein thrombosis (DVT) of lower left leg.

but a DVT is still suspected, a venogram may be needed to make an accurate diagnosis.

Impedance plethysmography assesses venous outflow and can detect most DVTs that are located above the popliteal vein. It is not helpful in locating clots in the calf and is less sensitive than Doppler studies.

Magnetic resonance direct thrombus imaging (MRI), another noninvasive test, is useful in finding a DVT in the proximal deep veins and is better than traditional venography in finding DVT in the inferior vena cava or pelvic veins.

A D-dimer test is a global marker of coagulation activation and measures fibrin degradation products produced from fibrinolysis (clot breakdown). The test is used for the diagnosis of DVT when the patient has few clinical signs and stratifies patients into a high-risk category for reoccurrence. Useful as an adjunct to noninvasive testing, a negative D-dimer test can exclude a DVT without an ultrasound.

Physical and diagnostic assessment of patients with pulmonary embolism is described in [Chapter 34](#).

INTERVENTIONS

The focus of managing thrombophlebitis is to prevent complications such as pulmonary emboli, prevent further thrombus formation, and prevent an increase in size of the thrombus. Patients with deep vein thrombosis (DVT) may be hospitalized for treatment, although this practice is changing as a result of the use of newer drugs.

Nonsurgical Management

DVT is usually treated medically using a combination of rest, drug therapy, and preventive measures. Prevention of DVT and other types of venous thromboembolism (VTE) is crucial for patients at risk. Preventive measures are listed on p. 799 in the Health Promotion and Maintenance section.

Rest. Supportive therapy for DVT has typically included bedrest and elevation of the extremity. However, a recent review and synthesis of the literature showed that outcomes are not different if the patient is allowed to ambulate (Gay et al., 2009). Ambulation did not cause pulmonary embolus; the DVT did not worsen any more with ambulation than bedrest. Allowing patients to ambulate may decrease their fear and anxiety about dislodging the clot and life-threatening complications.

Teach the patient to elevate his or her legs when in bed and chair. To help prevent chronic venous insufficiency, instruct patients with active and resolving DVT to wear knee- or thigh-high sequential or graduated compression stockings for an extended period. Be sure to select the correct stocking size for the patient according to the sizing chart provided.

Some health care providers prescribe intermittent or continuous warm, moist soaks to the affected area. *Do not massage the affected extremity to prevent the thrombus from dislodging and becoming an embolus.* Monitor all patients for signs and symptoms of pulmonary embolism (PE), which include shortness of breath, chest pain, and acute confusion (in older adults). Emboli may also travel to the brain or heart, but these complications are not as common as PE. [Chapter 34](#) describes PE manifestations in detail.

Drug Therapy. Anticoagulants are the drugs of choice for actual DVT and for patients at risk for DVT. The conventional treatment has been IV unfractionated heparin followed by oral anticoagulation with warfarin (Coumadin). However,

unfractionated heparin can be problematic because each patient's response to the drug is unpredictable and hospital admission is usually required for laboratory monitoring and dose adjustments. The use of low-molecular weight heparin (LMWH) is changing the management of both DVT and PE.

Unfractionated Heparin Therapy. Many patients with a confirmed diagnosis of an existing blood clot are started on a regimen of IV unfractionated heparin (UFH, Hepalean ) therapy. UFH is an anticoagulant agent that at low doses interacts with antithrombin III to produce selective inhibition of clotting factors IIa (thrombin) and Xa. At higher doses, it inhibits practically all clotting factors. The ultimate result is inhibition of fibrin formation. The physician prescribes UFH to prevent the formation of further clots, which often develop in the presence of an existing clot, and to prevent enlargement of the existing clot. Over a long period, the existing clot is slowly absorbed by the body.

Before UFH administration, a baseline prothrombin time (PT), activated partial thromboplastin time (APTT or aPTT), international normalized ratio (INR), complete blood count (CBC) with platelet count, urinalysis, stool for occult blood, and creatinine level are required. Notify the physician if the platelet count is below 120,000/mm³.

UFH is initially given in a bolus IV dose of about 80 to 100 units/kg of body weight or 5000 units followed by continuous infusion. The infusion is regulated by a reliable electronic pump that protects against accidental free flow of solution. The physician or clinical pharmacist prescribes concentrations of UFH (in 5% dextrose in water) and the number of units or milliliters per hour needed to maintain a therapeutic aPTT (usually 18–20 units/kg/hr or at least 30,000 units over 24 hours). aPTT is measured at least daily, and results are reported to the health care provider as soon as results are available to allow adjustment of heparin dosage. Therapeutic levels of aPTTs are usually 1½ to 2 times normal control levels.

! NURSING SAFETY PRIORITY

Drug Alert

Notify the physician if the aPTT value is greater than 70 seconds, or follow hospital protocol for reporting critical laboratory values. Assess patients for signs and symptoms of bleeding, which include hematuria, frank or occult blood in the stool, ecchymosis (bruising), petechiae, an altered level of consciousness, or pain. If bleeding occurs, stop the anticoagulant immediately and call the health care provider or Rapid Response Team!

UFH can also decrease platelet counts. Mild reductions are common and are resolved with continued heparin therapy. Severe platelet reductions, although rare, result from the development of antiplatelet bodies within 6 to 14 days after the beginning of treatment. Platelets aggregate into “white clots” that can cause thrombosis, usually in the form of an acute arterial occlusion. The provider discontinues heparin administration if severe **heparin-induced thrombocytopenia (HIT)** (platelet count <150,000), or “white clot syndrome,” occurs. Low-molecular weight heparin is used more commonly today because of the complications involved with unfractionated heparin.

Bivalirudin (Angiomax), lepirudin (Refludan), and argatroban (Arganova) are *highly selective direct thrombin*

CHART 38-7 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient Receiving Anticoagulant Therapy

- Carefully check the dosage of anticoagulant to be administered, even if the pharmacy prepared the drug.
- Monitor the patient for signs and symptoms of bleeding, including hematuria, frank or occult blood in the stool, ecchymosis, petechiae, altered mental status (indicating possible cranial bleeding), or pain (especially abdominal pain, which could indicate abdominal bleeding).
- Monitor vital signs frequently for decreased blood pressure and increased pulse (indicating possible internal bleeding).
- Have antidotes available as needed (e.g., protamine sulfate for heparin; vitamin K for warfarin [Coumadin, Warfilone]).
- Monitor activated partial thromboplastin time (aPTT) for patients receiving unfractionated heparin. Monitor prothrombin time (PT) or international normalized ratio (INR) for patients receiving warfarin or low-molecular weight heparin (LMWH).
- Apply prolonged pressure over venipuncture sites and injection sites.
- When administering *subcutaneous* heparin, apply pressure over the site and do not massage.
- Teach the patient going home while taking an anticoagulant to:
 - Use only an electric razor
 - Take precautions to avoid injury; for example, do not use tools such as hammers or saws, where accidents commonly occur
 - Report signs and symptoms of bleeding, such as blood in the urine or stool, nosebleeds, ecchymosis, or altered mental status
 - Take the prescribed dosage of drug at the precise time that it was prescribed to be given
 - Not stop taking the drug abruptly; the physician usually tapers the anticoagulant gradually

inhibitors that may be used as alternatives to heparin or for patients who have had HIT. Like heparin, these drugs increase the risk for bleeding. Monitor hemoglobin, hematocrit, aPTT, platelet count, urinalysis, fecal occult blood test, and blood pressure for indications of this complication. An oral anticoagulant like warfarin (Coumadin) may also be substituted for heparin if necessary.

Ensure that protamine sulfate, the antidote for heparin, is available if needed for excessive bleeding. [Chart 38-7](#) highlights information important to nursing care and patient education associated with anticoagulant therapy.

To *prevent* DVT, unfractionated heparin may be given in low doses subcutaneously for high-risk patients, especially after orthopedic surgery. Commonly used alternatives to unfractionated heparin include:

- Low-molecular weight heparin (e.g., enoxaparin [Lovenox]) (drug class of choice after orthopedic surgery)
- Selective factor Xa inhibitors (e.g., fondaparinux [Arixtra])
- Warfarin (Coumadin, Warfilone 🍀)

Low-Molecular Weight Heparin. Subcutaneous low-molecular weight heparins (LMWHs) such as enoxaparin (Lovenox), dalteparin (Fragmin), and ardeparin (Normiflo) have a consistent action and are preferred for prevention and treatment of DVT. Danaparoid (Orgaran) is also classified as an LMWH but is actually a heparinoid. LMWHs bind less to plasma proteins, blood cells, and vessel walls, resulting in a longer half-life and more predictable response. These drugs inhibit thrombin formation because of reduced factor IIa

activity and enhanced inhibition of factor Xa and thrombin.

Some patients taking LMWH may be safely managed at home with daily visits from a home care nurse. Candidates for home therapy must have stable DVT or PE, low risk for bleeding, adequate renal function, and normal vital signs. They must be willing to learn self-injection or have a family member, friend, or home care nurse administer the subcutaneous injections.

Some health care providers place the patient on a regimen of IV unfractionated heparin (UFH) for several days and then follow up with an LMWH. In this case, the UFH is discontinued at least 30 minutes before the first LMWH injection. The usual dose of enoxaparin is 1 mg/kg of body weight, not to exceed 90 mg, and is repeated every 12 hours. If the patient's creatinine level is greater than 2 mg/dL (indicating renal insufficiency), the health care provider lowers the dose. Dalteparin can be given once daily at 200 units/kg of body weight and does not require dose adjustment for renal insufficiency. The usual dose of ardeparin is 50 units/kg of body weight and is given every 12 hours.

Monitor the INR daily. Assess all stools for occult blood. The aPTTs are not checked on an ongoing basis because the doses of LMWH are not adjusted.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is providing care to a client at high risk for deep vein thrombosis. What health teaching will the nurse provide to the client related to home management of low-molecular weight heparin?

- "You must have your partial thromboplastin time checked every 2 weeks."
- "Massage the injection site after the heparin is injected."
- "Notify your health care provider if your stools appear tarry."
- "You will have an IV catheter placed for intermittent injection of the heparin."

Warfarin Therapy. If the patient is receiving continuous UFH, warfarin (Coumadin), an oral anticoagulant, may be added at least 5 days later. Patients receiving LMWH are placed on the oral drug after the first dose. Warfarin works in the liver to inhibit synthesis of the four vitamin K-dependent clotting factors and takes 3 to 4 days before it can exert therapeutic anticoagulation. The heparin continues to provide therapeutic anticoagulation until this effect is achieved. IV heparin is then discontinued.

Therapeutic levels of warfarin are monitored by measuring PT and/or the INR. Because PTs are often inconsistent and misleading, the INR was developed. Most laboratories report both results. Most patients receiving warfarin should have an INR between 1.5 and 2.0 to prevent future DVT and to minimize the risk for stroke or hemorrhage. For patients with additional cardiovascular problems, the desired INR

NURSING SAFETY PRIORITY

Drug Alert

For patients taking warfarin, assess for any bleeding, such as hematuria or blood in the stool. *Ensure that vitamin K, the antidote for warfarin, is available in case of excessive bleeding (see Chart 38-7).* Report any bleeding to the physician and document in the patient's health record.

may be higher. Warfarin therapy should be started with low doses, at least 5 mg, and gradually titrated up according to the INR. Patients usually receive this drug for 3 to 6 months or longer after an episode of DVT if no precipitating factors were discovered, with recurrence, or if there are continuing risk factors.

Thrombolytic Therapy. The use of systemic thrombolytic therapy for DVT is effective in dissolving thrombi quickly and completely. The greatest advantage is the prevention of valvular damage and venous insufficiency, or “post-phlebitis syndrome.” Thrombolytic therapy is contraindicated after surgery, trauma, strokes, or spinal injuries because of increased bleeding risks. To be most effective, thrombolytic therapy must be started within 5 days after the onset of symptoms.

Thrombolytic drugs such as recombinant tissue plasminogen activator (t-PA) and platelet inhibitors such as abciximab (ReoPro), tirofiban (Aggrastat), and eptifibatide (Integrilin) may be effective in dissolving a clot or preventing new clots during the first 24 hours. Infusion given via a catheter can be injected directly into the thrombus. Compared with giving systemic thrombolytic dosing, this approach decreases the concentration needed and reduces the chance of bleeding. Thrombolytic drugs, such as alteplase and reteplase, are used to treat peripheral vascular occlusion.

Reteplase is a plasminogen activator that penetrates the clot and causes lysis. *It is not compatible with heparin and should not be given in the same IV line.* Reteplase has been used successfully in treating coronary thrombosis. Use in peripheral vascular occlusion is experimental.

! NURSING SAFETY PRIORITY

Drug Alert

The most serious complication from thrombolytic therapy is intracerebral bleeding. Closely monitor patients for signs and symptoms of increasing intracranial pressure. A decreased level of consciousness (LOC) is the earliest indicator of this complication. Assess for other neurologic changes and report them immediately to the physician. Be sure to document the assessment findings in the patient's health record.

Surgical Management

A deep vein thrombus is rarely removed surgically unless there is a massive occlusion that does not respond to medical treatment and the thrombus is of recent (1 to 2 days) onset. **Thrombectomy** is the most common surgical procedure for removing the clot. Preoperative and postoperative care of patients undergoing thrombectomy is similar to the care for those undergoing arterial surgery (see pp. 789-790 in the **Peripheral Arterial Disease** section).

For patients with recurrent deep vein thrombosis (DVT) or pulmonary emboli that do not respond to medical treatment and for patients who cannot tolerate anticoagulation, **inferior vena cava filtration** may be indicated. The surgeon usually inserts a filter device, or “umbrella,” into the femoral vein. The device is meant to trap emboli in the inferior vena cava before they progress to the lungs. Holes in the device allow blood to pass through, thus not significantly interfering with the return of blood to the heart. There are several new filter brands available and designed to allow for removal if and when DVT risks diminish.

Preoperative care is similar to that provided for patients receiving local anesthesia (see **Chapter 16**). If they have recently been taking anticoagulants, collaborate with the physician about interrupting this therapy in the preoperative period to avoid hemorrhage.

Postoperatively, inspect the groin insertion site for bleeding and signs or symptoms of infection. Other postoperative nursing care is similar to that for any patient undergoing local anesthesia (see **Chapter 18**).

Community-Based Care

Patients recovering from thrombophlebitis or DVT are usually ambulatory when they are discharged from the hospital. The primary focus of planning for discharge is to educate the patient and family about the hazards of anticoagulation therapy.

Teach patients recovering from DVT to stop smoking and avoid the use of oral contraceptives to decrease the risk for recurrence. Alternative forms of birth control may be used. Most patients are discharged on a regimen of warfarin (Coumadin, Warfilone ) or low-molecular weight heparin (LMWH). Instruct patients and their families to avoid potentially traumatic situations, such as participation in contact sports. Provide written and oral information about the signs and symptoms of bleeding (see **Chart 38-7**). Reinforce the need to report any of these manifestations to the health care provider immediately.

The anticoagulant effect of warfarin may be reversed by omitting one or two doses of the drug or by the administration of vitamin K. In case of injury, teach patients to apply pressure to bleeding wounds and to seek medical assistance immediately. Encourage them to carry an identification card or wear a medical alert bracelet that states that they are taking warfarin or any other anticoagulant.

Instruct patients to tell their dentist and other health care providers that they are taking warfarin before receiving treatment or prescriptions. Prothrombin times are affected by many prescription and over-the-counter drugs such as NSAIDs. Teach patients to avoid high-fat and vitamin K-rich foods, such as cabbage, cauliflower, broccoli, asparagus, turnips, spinach, kale, fish, and liver (**Chart 38-8**). Remind them to drink adequate fluids to stay well hydrated, avoid alcohol (which can cause dehydration), and avoid sitting for prolonged periods.

In collaboration with the case manager (CM) or other discharge planner, arrange for patients to obtain a device to self-monitor INR at home. Clinical studies show that self-monitoring of the INR and self-adjusting of anticoagulation therapy result in better anticoagulation control, improve patient satisfaction, and increase quality of life (Levi, 2008). The device used to self-monitor is similar to a glucometer for glucose testing and requires a fingerstick blood sample applied to a test strip or plastic cuvette, which is then inserted into the machine. Self-monitoring can be used either for the testing alone or for self-management, in which the patient uses the test results to adjust drug dosages based on a dosing protocol (Levi, 2008). If the patient cannot use a monitoring device, teach a family member or other caregiver how to perform the procedure. If the patient lives alone, collaborate with the CM to arrange for follow-up laboratory appointments to have blood drawn at frequent intervals—usually every week until the patient's values are stabilized.

CHART 38-8 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Food and Drugs That Interfere with Warfarin (Coumadin)

Eat small amounts of foods rich in vitamin K each day, including any of these:	If possible, avoid:
• Broccoli • Cauliflower • Spinach • Kale • Green leafy vegetables • Brussels sprouts • Cabbage • Liver	• Allopurinol • NSAIDs • Acetaminophen • Vitamin E • Histamine blockers • Cholesterol-reducing drugs • Antibiotics • Oral contraceptives • Antidepressants • Thyroid drugs • Antifungal agents • Other anticoagulants • Corticosteroids • Herbs, such as St. John's wort, garlic, ginseng, <i>Ginkgo biloba</i>

Patients receiving subcutaneous LMWH injections at home need instruction on self-injection. Teach the appropriate caregiver and family members or friends, if necessary, to administer the injections.

Patients who have experienced DVT may fear recurrence of a thrombus. They may also be concerned about treatment with warfarin and the risk for bleeding. Assure them that the prescribed treatment will help resolve this problem and that ongoing assessment of prothrombin times and INR values decreases the risks for bleeding.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client is being discharged home on warfarin (Coumadin) after being treated for deep vein thrombosis. What priority instruction will the nurse include in the client's discharge teaching?

- "Take one extra Coumadin the day before a blood test."
- "Eat a diet high in protein and green leafy vegetables."
- "Use a soft-bristled toothbrush to prevent bleeding of the gums."
- "Weigh yourself daily at the same time to monitor fluid balance."

VENOUS INSUFFICIENCY

Pathophysiology

Venous insufficiency occurs as a result of prolonged venous hypertension that stretches the veins and damages the valves. Valvular damage can lead to a backup of blood and further venous hypertension, resulting in edema and decreased tissue perfusion. With time, this stasis (stoppage) results in venous stasis ulcers, swelling, and cellulitis.

The veins cannot function properly when thrombosis occurs or when valves are not working correctly. Venous hypertension can occur in people who stand or sit in one position for long periods (e.g., teachers, office personnel). Obesity can also cause chronically distended veins, which lead to damaged valves. Thrombus formation can contribute to valve destruction. Chronic venous insufficiency also often

occurs in patients who have had thrombophlebitis. In severe cases, venous ulcers develop.

Venous leg ulcers are a major cause of death, pain, and health care costs. Most venous ulcer care is delivered in the community setting by home care nurses or through self-management.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Venous insufficiency may result in edema of both legs. There may be **stasis dermatitis** or reddish brown discoloration along the ankles, extending up to the calf. In people with long-term venous insufficiency, **stasis ulcers** often form. They can result from the edema or from minor injury to the limb. Ulcers typically occur over the malleolus, more often medially (inner ankle) than laterally (outer ankle). The ulcer usually has irregular borders. In general, these ulcers are chronic and difficult to heal (see [Chart 38-4](#)). Many people live with ulcers for years, and recurrence is common. Some may lose one or both legs if ulcers are not controlled.

INTERVENTIONS

The focus of treating venous insufficiency is to decrease edema and promote venous return from the affected leg. Patients are not usually hospitalized for venous insufficiency alone unless it is complicated by an ulcer or another disorder is occurring at the same time.

Nonsurgical Management

Treatment of chronic venous insufficiency is nonsurgical unless it is complicated by a venous stasis ulcer that requires surgical débridement. The desired outcomes of managing venous stasis ulcers are to heal the ulcer, prevent infection, and prevent stasis with recurrence of ulcer formation. Collaborate with the wound care nurse or wound, ostomy, and continence nurse to make recommendations for ulcer care. A dietitian can suggest dietary supplements, such as zinc and vitamins A and C, as well as high-protein foods, to promote wound healing.

Patients with chronic venous insufficiency wear graduated compression stockings, which fit from the middle of the foot to just below the knee or to the thigh. Stockings should be worn during the day and evening. Explain the purpose and importance of wearing the compression stockings. Winslow and Brosz (2008) found that a number of hospitalized patients do not use these stockings correctly and that over a quarter of patients had the wrong size. Be sure to use the sizing chart that comes with the stockings to select the best fit. Teach patients to not roll them down and to report if they become too tight or uncomfortable.

Teach the patient to elevate his or her legs for at least 20 minutes four or five times per day. When the patient is in bed, remind him or her to elevate the legs above the level of the heart ([Chart 38-9](#)).

Coordinate with the physician about the use of intermittent sequential pneumatic compression or foot plexus pumps for patients with past or present venous stasis ulcers. If an open venous ulcer is present, the device may be applied over a dressing such as an Unna boot. Instruct the patient to apply

CHART 38-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Venous Insufficiency

Graduated Compression Stockings

- Wear stockings as prescribed, usually during the day and evening.
- Put the stockings on upon awakening and before getting out of bed.
- When applying the stockings, do not “bunch up” and apply like socks. Instead, place your hand inside the stocking and pull out the heel. Then place the foot of the stocking over your foot and slide the rest of the stocking up. Be sure that rough seams on the stocking are on the outside, not next to your skin.
- Do not push stockings down for comfort, because they may function like a tourniquet and further impair venous return.
- Put on a clean pair of stockings each day. Wash them by hand (not in a washing machine) in a gentle detergent and warm water.
- If the stockings seem to be “stretched out,” replace them with a new pair.

Dos and Don'ts

- Elevate your legs for at least 20 minutes four or five times a day. When in bed, elevate your legs above the level of your heart.
- Avoid prolonged sitting or standing.
- Do not cross your legs. Crossing at the ankles is acceptable for short periods.
- Do not wear tight, restrictive pants. Avoid girdles and garters.

the pump as directed during the period of healing. Because of the high incidence of venous ulcer recurrence, encourage patients with chronic venous insufficiency whose ulcers have healed to continue compression therapy for life.

Venous stasis ulcers are slightly more manageable than ulcers resulting from arterial disease. They are chronic in nature, with some patients having the same ulcer for years. Ulcers often heal, only to recur in the same area several years later.

Two types of occlusive dressings are used for venous stasis ulcers: oxygen-permeable dressings and oxygen-impermeable dressings. Because the role of atmospheric oxygen in wound healing is controversial, opinions vary with regard to which type of dressing is preferred. An oxygen-permeable polyethylene film and an oxygen-impermeable hydrocolloid dressing (e.g., DuoDERM) are common. Hydrocolloid dressings are left in place for a minimum of 3 to 5 days for best effect. Use medical aseptic technique when changing dressings. If the wound is infected, use Contact Precautions in addition to Standard Precautions.

Artificial skin products can be used for difficult-to-heal venous leg ulcers. These first-generation products are very expensive but are laying the foundation in the field, with costs anticipated to come down in the future. Except for cultured epithelial autografts, artificial skins are only temporary. Artificial skin serves as a biologic cover to secrete growth factors to promote more growth factor secretion from the patient's own skin to speed the wound healing process.

If the patient is ambulatory, an **Unna boot** may be used. An Unna boot dressing is constructed of gauze that has been moistened with zinc oxide. Apply the boot to the affected limb, from the toes to the knee, after the ulcer has been cleaned with normal saline solution. It is then covered with

an elastic wrap and hardens like a cast. This promotes venous return and prevents stasis. The Unna boot also forms a sterile environment for the ulcer. The physician or advanced practice nurse changes the boot about once a week. Instruct the patient to report increased pain, which indicates that the boot may be too tight.

The health care provider may prescribe topical agents, such as Accuzyme, to chemically debride the ulcer, eliminating necrotic tissue and promoting healing. Remind patients that they may temporarily feel a burning sensation when the agent is applied. If an infection or cellulitis develops, systemic antibiotics are necessary.

Surgical Management

Surgery for chronic venous insufficiency is not usually performed because it is not successful. Attempts at transplanting vein valves have had limited success. Surgical débridement of venous ulcers is similar to that performed for arterial ulcers.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

The nurse is caring for a client with chronic venous stasis ulcers. Which priority health teaching will the nurse include in this client's continuing plan of care?

- “Wear compression stockings every day.”
- “Do not elevate the affected leg above your heart.”
- “Take one low-dose aspirin daily to prevent inflammation.”
- “Clean the ulcers with Betadine to prevent infection.”

Community-Based Care

The desired outcome for the patient with chronic venous insufficiency is to be managed in the home. For patients with frequent acute complications and repeated hospital admissions, case management can help meet appropriate clinical and cost outcomes.

Help patients plan for opportunities and facilities that allow for elevation of the lower extremities in and outside the home. In addition, collaborate with the wound specialist to plan care of the ulcers at home.

If the physician prescribes graduated compression stockings, teach patients to apply these stockings before they get out of bed in the morning and to remove them just before going to bed at night (see [Chart 38-9](#)). Also advise them that they will probably need to wear these stockings for the rest of their lives.

To improve circulation and aid in weight reduction, collaborate with the physical therapist to prescribe an exercise program on an individual basis. Encourage all patients to maintain an optimal weight and consult with the dietitian to plan a weight-reduction diet.

Patients with venous stasis disease, especially those with venous stasis ulcers, may require long-term emotional support to assist them in meeting long-term needs. They may also need assistance in coping with necessary lifestyle adjustments, such as possible changes in occupation.

Patients with venous stasis ulcers may need the assistance of a home care nurse to perform dressing changes. Those with Unna boots need weekly transportation to their health care provider for dressing changes. Collaborate with the case

manager to arrange for a sequential compression device in the home if the health care provider prescribes one.

VARICOSE VEINS

Pathophysiology

Varicose veins are distended, protruding veins that appear darkened and tortuous. They can occur in anyone, but they are common in adults older than 30 years whose occupations require prolonged standing. Varicose veins are frequently seen also in patients with systemic problems (e.g., heart disease), obesity, and a family history of varicose veins.

As the vein wall weakens and dilates, venous pressure increases and the valves become incompetent (defective). The incompetent valves enhance the vessel dilation, and the veins become tortuous and distended. The patient may report pain, especially after standing, and may experience a feeling of fullness in the legs. Nursing assessment reveals distended, protruding veins.

The Trendelenburg test assists with the diagnosis for patients who are not of advanced age. Place the patient in a supine position with elevated legs. As he or she sits up, the veins would normally fill from the distal end. However, if there are varicosities, the veins fill from the proximal end.

PATIENT-CENTERED COLLABORATIVE CARE

Conservative measures are the treatment of choice, including graduated compression stockings and elevating the extremities as much as possible. Patients who continue to have pain or unsightly veins, despite this treatment, may opt for either sclerotherapy or surgical removal of the vein.

Sclerotherapy is performed on small or a limited number of varicosities. The physician injects a sclerosing solution directly into the vein. A pressure dressing may be applied over the sclerosed vein to keep vessels free of blood for 24 to 72 hours. The surgeon performs an incision and drainage of trapped blood in the sclerosed vein 14 to 21 days after injection, followed by application of a second pressure dressing for 12 to 18 hours.

Varicose veins are surgically removed when they are larger than 4 mm in diameter or are in clusters. The stab avulsion technique may be used if the saphenous veins are competent. The surgeon exposes varices through 2- to 3-mm stab incisions, grasping the veins with hooks and dividing and removing each vein.

The surgeon may need to strip (remove) affected veins if the saphenous vein is affected. The surgeon threads a long wire through an incision above an affected vein, pulling it down through the vein and out through an incision below the vein. After this procedure, the legs are bandaged with firm elastic bandages.

After surgery, assess the groin and entire leg for bleeding through the elastic bandage. Instruct the patient to keep the legs elevated and to perform range-of-motion exercises of the legs at least hourly. Patients are ambulatory and are often discharged from the hospital by the first postoperative day. At this time, instruct them to continue to wear elastic stockings,

walk, limit sitting, avoid standing in one place, and elevate their legs when sitting.

Application of radiofrequency (RF) energy is a new technique done as an alternative to surgery. The vein is heated from the inside by the RF energy and shrinks. Collateral veins nearby take over.

Laser treatment is another alternative to surgery. Performed by interventional radiologists, the endovenous laser treatment uses a laser fiber to heat and close the main vessel that is contributing to the varicosity.

PHLEBITIS

Phlebitis is an inflammation of the superficial veins caused by an irritant such as peripheral IV therapy (see [Chapter 15](#)). The patient has a reddened, warm area radiating up the arm. Pain, soreness, and swelling may also occur.

Management involves application of warm, moist soaks, which dilate the vein and promote circulation. Sometimes a heating unit is used to keep the soaks warm. Apply the soaks, making sure that the temperature is not hot enough to burn the patient, and assess for complications, such as tissue necrosis, infection, or pulmonary embolus. After a few days of conservative therapy, the inflammation usually subsides. Graduated compression stockings may be prescribed if the phlebitis occurs in a leg.

VASCULAR TRAUMA

Many types of trauma can result in vascular injury. Vascular injuries include punctures, lacerations, and transections. Acute blunt or penetrating trauma may result in a false aneurysm or hematoma. Arteriovenous fistulas may be seen after penetrating injuries. The more common causes of penetrating injuries to the blood vessels are gunshot and knife wounds.

Blunt trauma can result from high-speed automobile crashes as a result of the shearing force of rapid deceleration. Vascular trauma can also occur during arterial puncture for arteriographic or hemodynamic studies in which a dissection, hematoma, or occlusive lesion occurs.

The history and physical examination aid in establishing the diagnosis of vascular injury. Ask the patient or family about the mechanism of injury, the site of injury, the amount of blood loss, and symptoms present after the injury. Assess for circulatory, sensory, and motor impairment. Be aware that, despite significant trauma, impairment may not be apparent, especially if deep vessels have been injured. Arteriography can provide essential information about the vascular injury.

Management of vascular injuries is often initiated in a hospital emergency department. Careful patient triage is crucial. The most important principles in the management of vascular trauma are establishing a patent airway, controlling bleeding, and restoring blood flow. Emergency or urgent surgical intervention is needed for ischemia to maximize successful revascularization.

The method of repair varies with the type of vascular injury. Techniques include vein bypass grafting, lateral suture repair, thrombectomy (excision of blood clot), resection with end-to-end anastomosis, and vein patch grafting.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of vascular problems?

- Redness and swelling in lower leg (venous)
- Pallor, cyanosis (darkened), mottling, or rubor in lower leg (arterial)
- Report of pain/cramping in lower legs or hands (at rest or during activity)
- Ulcers on ankles, feet, or digits
- Pulsating mass in abdomen (abdominal aortic aneurysm)
- Decreased level of consciousness (LOC), diaphoresis, decreased urine output (rupturing aortic aneurysm)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of peripheral vascular disease?

Perform and interpret physical assessment, including:

- Taking vital signs

- Assessing peripheral pulses
- Assessing capillary refill
- Checking for sensation and temperature
- Completing a pain assessment
- Assessing ulcer

Respond by:

- Notifying physician immediately or calling Rapid Response Team if aortic rupture suspected
- Monitoring vital signs
- Giving oxygen if aneurysm rupture suspected
- Starting an IV line if aneurysm rupture suspected
- Documenting abnormal peripheral vascular assessment findings
- Elevating legs if swollen unless arterial blood flow is poor

On what should you REFLECT?

- Think about how you responded.
- Continue to monitor patient for changes in peripheral blood flow, including pulse assessments.
- Observe patient for decreased report of pain.

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Plan care for the patient with atherosclerosis and hypertension, in collaboration with the health care team, including the dietitian and pharmacist as needed.
- To reduce the risk for injury, caution patients about orthostatic hypotension when taking antihypertensive drugs.

Health Promotion and Maintenance

- In collaboration with the dietitian, assist the patient to incorporate healthy eating behaviors to lower cholesterol and saturated fats and increase fresh fruits, vegetables, and fiber in the diet. For overweight patients, assist in a weight-reduction plan.
- Teach patients ways to prevent deep vein thrombosis and subsequent embolism. In the hospital setting, provide measures, such as wearing graduated compression stockings, to prevent or manage DVT.
- Assess the patient for modifiable and nonmodifiable risk factors for vascular disease, and teach health promotion behaviors to the patient and family. Pay particular attention to the patient with a family history of cardiovascular disease (see [Table 38-1](#)).

Physiological Integrity

- Remember that risk factors such as smoking increase the pathophysiologic process of atherosclerosis.

- Recall the classifications for hypertension to identify patients who are prehypertensive and those who need referral to a health care provider (see [Table 38-3](#)).
- Hypertension is categorized as either essential or secondary; the risk factors and causes for each type are described in [Table 38-5](#).
- Closely observe the patient receiving anticoagulants or thrombolytics for signs of bleeding, and monitor appropriate laboratory values for desired outcome values (see [Chart 38-7](#)).
- Monitor for decreased serum potassium levels when patients are taking thiazide or loop diuretics (see [Chart 38-1](#)).
- Teach patients to move slowly when changing position if taking any of the antihypertensive drugs listed in [Chart 38-1](#).
- Teach patients taking any of the statins in [Table 38-2](#) to report any adverse effects including muscle cramping to their health care provider. Monitor the patient's liver enzymes carefully.
- Provide emergency care for the patient having a hypertensive crisis as described in [Chart 38-2](#).
- Recognize that clinical manifestations of peripheral vascular disease (PVD) depend on whether it affects the arteries or veins. In addition to pallor, rubor, or cyanosis, key features of chronic peripheral arterial disease are listed in [Chart 38-3](#).
- Vasodilating drugs or surgery is used for arterial vascular diseases.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Deep vein thrombosis is the most common type of peripheral vascular problem. When symptoms are present, they include swelling, redness, localized pain, and warmth.
- Teach patients about self-care when they have venous insufficiency.
- Assess for venous and arterial ulcers as described in [Chart 38-4](#).
- Teach foot care for patients with PVD as outlined in [Chart 38-6](#).
- Teach patients about precautions for anticoagulant therapy as described in [Chart 38-7](#). Teach about food and drugs that interfere with warfarin (Coumadin) as listed in [Chart 38-8](#).
- Monitor for indications of aneurysm rupture: diaphoresis, nausea, vomiting, pallor, hypotension, tachycardia, severe pain, and decreased level of consciousness.
- Essential hypertension is called *primary hypertension* and is not caused by another health problem or drug. *Secondary hypertension* is caused by other health problems or drug therapy (see [Table 38-5](#)).

Concept Map Creator

Concept Map: Hypovolemic Shock
Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Evaluate patient risk for hypovolemic shock or sepsis and septic shock.
2. Ensure vital sign measurements are accurate, and monitor them for changes indicating the presence of shock.
3. Apply principles of infection control to prevent infection and sepsis in susceptible patients, especially older adults.

Health Promotion and Maintenance

4. Teach all people to avoid dehydration.
5. Teach all people to use safety devices to avoid trauma.
6. Instruct all patients going home after surgery or invasive procedures to seek immediate attention for persistent manifestations of early shock.
7. Teach all patients who have a local infection to seek medical attention when manifestations of systemic infection appear.

Psychosocial Integrity

8. Assess the vital signs, especially pulse and oxygen saturation, for any patient who has a sudden change in

mental status, including increased anxiety, apprehension, or agitation.

9. Reassure the patient in shock that the appropriate interventions are being implemented.

Physiological Integrity

10. Compare the risk factors, causes, and manifestations of different types of shock.
11. Identify the manifestations associated with shock progression.
12. Use laboratory data and clinical manifestations to determine the effectiveness of therapy for shock.
13. Describe the actions, side effects, and nursing implications of drug therapy for shock.
14. Coordinate the nursing care for the patient experiencing any stage of hypovolemic shock.
15. Explain the role of the systemic inflammatory response syndrome (SIRS) in the manifestations and progression of sepsis and septic shock.
16. Prioritize the nursing care for the patient with sepsis or septic shock.

OVERVIEW

A continuous supply of oxygen is needed by all organs, tissues, and cells to function properly. The lungs first bring oxygen into the body, and the cardiovascular system (heart, blood, and blood vessels) delivers oxygen to all tissues and removes cellular wastes (Fig. 39-1). **Shock** is widespread abnormal cellular metabolism that occurs when *oxygenation and tissue perfusion* needs are not met to the level necessary to maintain cell function (McCance et al., 2010). It is a condition rather than a disease and represents the “whole-body” response that occurs when too little oxygen is delivered to the tissues. All body organs are affected by shock and either work harder to adapt and compensate for reduced oxygenation (see Fig. 39-1) or fail to function because of hypoxia. Shock is a “syndrome” because the cellular, tissue, and organ events occur in a predictable sequence.

Any problem that impairs oxygen delivery to tissues and organs can start the syndrome of shock and lead to a life-threatening emergency. Most often, shock is a result of cardiovascular problems and changes. Patients in acute care settings are at higher risk, but shock can occur in any setting. For example, older patients in long-term care settings are at risk for sepsis and shock related to urinary tract infections. When the body’s adaptive adjustments (compensation) or health care interventions are not effective and shock progresses, severe hypoxia can lead to cell loss, multiple organ dysfunction syndrome (MODS), and death.

Shock is classified by the functional impairment it causes into the categories of hypovolemic shock, cardiogenic shock,

distributive shock (which includes septic shock, neurogenic shock, and anaphylactic shock), and obstructive shock. Table 39-1 describes the functional impairment classification and common causes of shock.

Most manifestations of shock are similar regardless of what starts the process or which tissues are affected first. These common manifestations result from physiologic adjustments (*compensatory mechanisms*) in the attempt to ensure continued oxygenation of vital organs. These adjustment actions are performed by the sympathetic nervous system, triggering the stress response and activating the endocrine and cardiovascular systems. Manifestations unique to any one type of shock result from specific tissue dysfunction. The common features of shock are listed in Chart 39-1.

Review of Oxygenation and Tissue Perfusion

Oxygenation and perfusion depend on how much oxygen from arterial blood perfuses the tissue. Tissue and organ perfusion is related to mean arterial pressure (MAP). Because the cardiovascular system is a closed but continuous circuit, the factors that influence MAP include:

- Total blood volume
- Cardiac output
- Size of the vascular bed

Total blood volume and cardiac output are directly related to MAP, so increases in either total blood volume or cardiac output *raise* MAP. Decreases in either total blood volume or cardiac output *lower* MAP.

The size of the vascular bed is inversely (negatively) related to MAP. This means that increases in the size of the vascular

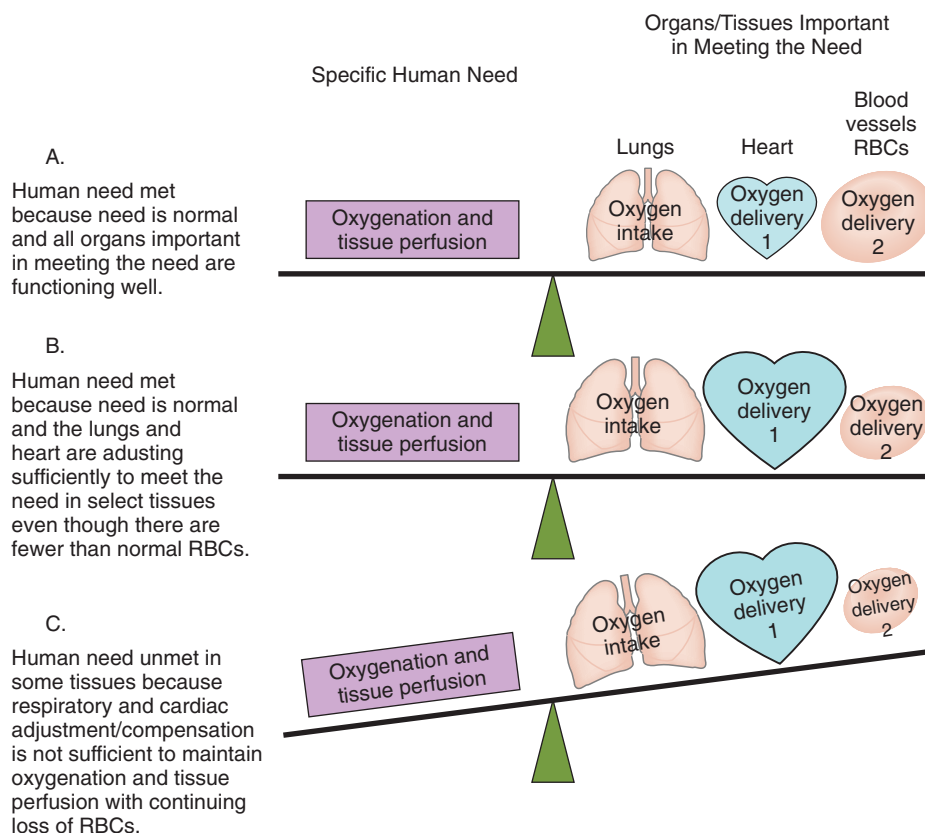

FIG. 39-1 Oxygenation and tissue perfusion affected by hypovolemic shock and adjustment/compensation. RBCs, Red blood cells.

TABLE 39-1 CAUSES AND TYPES OF SHOCK BY FUNCTIONAL IMPAIRMENT

Hypovolemic Shock**Overall Cause**

Total body fluid decreased (in all fluid compartments).

Specific Cause or Risk Factors

Hemorrhage

- Trauma
- GI ulcer
- Surgery
- Inadequate clotting
 - Hemophilia
 - Liver disease
- Malnutrition
- Bone marrow suppression
- Cancer
- Anticoagulation therapy

Dehydration

- Vomiting
- Diarrhea
- Heavy diaphoresis
- Diuretic therapy
- Nasogastric suction
- Diabetes insipidus
- Hyperglycemia

Cardiogenic Shock**Overall Cause**

Direct pump failure (fluid volume not affected).

Specific Cause or Risk Factors

Myocardial infarction

Cardiac arrest

Ventricular dysrhythmias

- Fibrillation
- Tachycardia

Cardiac amyloidosis

Cardiomyopathies

- Viral
- Toxic

Myocardial degeneration

Distributive Shock**Overall Cause**

Fluid shifted from central vascular space (total body fluid volume normal or increased).

Specific Cause or Risk Factors

Neural-induced

- Pain
- Anesthesia
- Stress
- Spinal cord injury
- Head trauma

Chemical-induced

- Anaphylaxis
- Sepsis
- Capillary leak
 - Burns
 - Extensive trauma
 - Liver impairment
- Hypoproteinemia

Obstructive Shock**Overall Cause**

Cardiac function decreased by noncardiac factor (indirect pump failure).
Total body fluid is not affected although central volume is decreased.

Specific Cause or Risk Factors

Cardiac tamponade

Arterial stenosis

Pulmonary embolus

Pulmonary hypertension

Constrictive pericarditis

Thoracic tumors

Tension pneumothorax

CHART 39-1 KEY FEATURES

Shock**Cardiovascular Manifestations**

- Decreased cardiac output
- Increased pulse rate
- Thready pulse
- Decreased blood pressure
- Narrowed pulse pressure
- Postural hypotension
- Low central venous pressure
- Flat neck and hand veins in dependent positions
- Slow capillary refill in nail beds
- Diminished peripheral pulses

Respiratory Manifestations

- Increased respiratory rate
- Shallow depth of respirations
- Increased P_{aCO_2}
- Decreased P_{aO_2}
- Cyanosis, especially around lips and nail beds

Neuromuscular Manifestations**Early**

- Anxiety
- Restlessness
- Increased thirst

Late

- Decreased central nervous system activity (lethargy to coma)
- Generalized muscle weakness
- Diminished or absent deep tendon reflexes
- Sluggish pupillary response to light

Kidney Manifestations

- Decreased urine output
- Increased specific gravity
- Sugar and acetone present in urine

Integumentary Manifestations

- Cool to cold
- Pale to mottled to cyanotic
- Moist, clammy
- Mouth dry; pastelike coating present

Gastrointestinal Manifestations

- Decreased motility
- Diminished or absent bowel sounds
- Nausea and vomiting
- Constipation

FIG. 39-2 Interaction of blood volume and the size of the capillary bed affecting mean arterial pressure (MAP).

bed *lower* MAP and decreases *raise* MAP (Fig. 39-2). The small arteries and veins connected to capillaries can increase in diameter by relaxing the smooth muscle in vessel walls (**dilation**) or decrease in diameter by contracting the muscle (**vasoconstriction**). When blood vessels dilate and total blood volume remains the same, blood pressure decreases and blood flow is slower. When blood vessels constrict and total blood volume remains the same, blood pressure increases and blood flow is faster.

Blood vessels are innervated by the sympathetic division of the autonomic nervous system. Some nerves continuously stimulate vascular smooth muscle so that the blood vessels are normally partially constricted, a condition called **sympathetic tone**. Increases in sympathetic stimulation constrict smooth muscle even more, raising MAP. Decreases in sympathetic tone relax smooth muscle, dilating blood vessels and lowering MAP.

Blood flow to organs varies and adjusts to changes in tissue oxygen needs. The body can selectively increase blood flow to some areas while reducing blood flow to others. The skin and skeletal muscles can tolerate low levels of oxygen for hours without dying or being damaged. Other organs (e.g., heart, brain, liver, pancreas) do not tolerate **hypoxic** (low levels of

tissue oxygenation), and only a few minutes without oxygen results in serious damage and cell death.

Types of Shock

Types of shock and their causes vary because shock is a manifestation of a pathologic condition rather than a disease state (see Table 39-1). *More than one type of shock can be present at the same time.* For example, trauma caused by a car crash may trigger hemorrhage (leading to hypovolemic shock) and a myocardial infarction (leading to cardiogenic shock).

Hypovolemic shock occurs when too little circulating blood volume causes a MAP decrease, resulting in inadequate total body oxygenation. Common problems leading to hypovolemic shock are hemorrhage and dehydration. A complete discussion of the pathophysiology and management of hypovolemic shock begins on p. 812.

Cardiogenic shock occurs when the actual heart muscle is unhealthy and pumping is directly impaired. Myocardial infarction is the most common cause of direct pump failure (Held & Sturtz, 2009). Other causes are listed in Table 39-1. Any type of pump failure decreases cardiac output and MAP. Chapter 40 discusses the pathophysiology and care

for the person with cardiogenic shock from myocardial infarction.

Distributive shock occurs when blood volume is not lost from the body but is distributed to the interstitial tissues where it cannot circulate and deliver oxygen. It can be caused by a loss of sympathetic tone, blood vessel dilation, pooling of blood in venous and capillary beds, and increased capillary leak. All these factors can decrease mean arterial pressure (MAP) and may be started by nerve changes (*neural-induced*) or the presence of some chemicals (*chemical-induced*).

Neural-induced distributive shock is a loss of MAP that occurs when sympathetic nerve impulses controlling blood vessel smooth muscle are decreased and the smooth muscles relax, causing vasodilation. This blood vessel dilation can be a normal local response to injury, but shock results when vasodilation is widespread (King & Olson, 2007). Problems leading to loss of sympathetic tone are listed in Table 39-1.

Chemical-induced distributive shock has three common origins: anaphylaxis, sepsis, and capillary leak syndrome. It occurs when certain body chemicals or foreign substances in the blood and vessels start widespread changes in blood vessel walls. The chemicals are usually **exogenous** (originate outside the body), but this type of shock also can be induced by substances normally found in the body (**endogenous**), such as excessive amounts of the mediator *histamine*.

Anaphylaxis is one result of type I allergic reactions. It begins within seconds to minutes after exposure to a specific allergen in a susceptible person. The result is widespread loss of blood vessel tone and decreased cardiac output. Table 22-2 (in Chapter 22) lists common allergens that can cause anaphylaxis. Chapter 22 describes the pathophysiology, prevention, and care of the patient with anaphylactic shock.

Sepsis is a widespread infection that triggers a whole-body inflammatory response. It leads to distributive shock when infectious microorganisms are present in the blood. This form of shock is most commonly called **septic shock**. A complete discussion of the pathophysiology, prevention, and collaborative care for the patient with sepsis and septic shock begins on p. 819.

Capillary leak syndrome is the response of capillaries to the presence of biologic mediators that change blood vessel integrity and allow fluid to shift from the blood vessels into the interstitial tissues. Once in the interstitial tissue, these fluids are stagnant and cannot deliver oxygen or remove tissue waste products. Fluid shifts result from increased size of capillary pores, loss of plasma osmolarity, and increased hydrostatic pressure in the blood. Problems causing fluid shifts include severe burns, liver disorders, ascites, peritonitis, paralytic ileus, severe malnutrition, large wounds, hyperglycemia, kidney disease, hypoproteinemia, and trauma.

Obstructive shock is caused by problems that impair the ability of the normal heart muscle to pump effectively. The heart itself remains normal, but conditions outside the heart prevent either adequate filling of the heart or adequate contraction of the healthy heart muscle. The most common causes of obstructive shock are pericarditis and cardiac tamponade (see Table 39-1). Care of the person with cardiac tamponade is presented in detail in Chapter 37 (pericarditis) and Chapter 40 (as a complication after cardiac bypass graft surgery).

*Although the causes and initial manifestations associated with the different types of shock vary, eventually the effects of hypotension and **anaerobic cellular metabolism** (metabolism without oxygen) result in the common key features of shock listed in Chart 39-1. The origin of these features is explained below in the discussion of Pathophysiology in the Hypovolemic Shock section.*

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Why are the manifestations of most types of shock the same regardless of what specific events or condition caused the shock to occur?

- A. The blood, blood vessels, and heart are directly connected to each other so that when one is affected, all three are affected.
- B. Because blood loss occurs with all types of shock, the most common first manifestation is hypotension.
- C. Every type of shock interferes with oxygenation and metabolism of all cells in the same sequence.
- D. The sympathetic nervous system is triggered by any type of shock and initiates the stress response.

HYPOVOLEMIC SHOCK

Pathophysiology

The basic problem of hypovolemic shock is a loss of blood volume from the vascular space, resulting in a decreased mean arterial pressure (MAP) (see Fig. 39-2) and a loss of oxygen-carrying capacity from the loss of circulating red blood cells (RBCs). The reduced MAP slows blood flow, resulting in decreased tissue perfusion. The loss of RBCs decreases the ability of the blood to oxygenate the tissue it does reach. These oxygenation and perfusion problems lead to cellular *anaerobic* (without oxygen) conditions and abnormal cellular metabolism.

The main trigger leading to hypovolemic shock is a sustained decrease in MAP that results from decreased circulating blood volume. A decrease in MAP of 5 to 10 mm Hg below the patient's normal baseline value is detected by pressure-sensitive nerve receptors (*baroreceptors*) in the aortic arch and carotid sinus. This information is transmitted to brain centers, which stimulate adjustments (*compensatory mechanisms*) that help ensure continued blood flow and oxygen delivery to vital organs while limiting blood flow to less vital areas. The movement of oxygenated blood into selected areas while bypassing others ("shunting") results in some shock manifestations.

If the events that caused the initial decrease in MAP are halted now, compensatory mechanisms provide adequate oxygenation and perfusion without outside intervention. If the initiating events continue and MAP decreases further, some tissues function under anaerobic conditions. This condition increases lactic acid levels and other harmful metabolites (e.g., protein-destroying enzymes, oxygen free radicals). These substances cause electrolyte and acid-base imbalances with tissue-damaging effects and depressed heart muscle activity. These effects are temporary and reversible if the cause of shock is corrected within 1 to 2 hours after onset. When shock conditions continue for longer periods without help, the resulting acid-base imbalance, electrolyte

TABLE 39-2 ADAPTIVE RESPONSES AND EVENTS DURING HYPOVOLEMIC SHOCK**Initial Stage**

- Decrease in baseline mean arterial pressure (MAP) of 5-10 mm Hg
- Increased sympathetic stimulation
 - Mild vasoconstriction
 - Increased heart rate

Nonprogressive Stage

- Decrease in MAP of 10-15 mm Hg from the patient's baseline value
- Continued sympathetic stimulation
 - Moderate vasoconstriction
 - Increased heart rate
 - Decreased pulse pressure
- Chemical compensation
 - Renin, aldosterone, and antidiuretic hormone secretion
 - Increased vasoconstriction
 - Decreased urine output
 - Stimulation of the thirst reflex
- Some anaerobic metabolism in nonvital organs
 - Mild acidosis
 - Mild hyperkalemia

Progressive Stage

- Decrease in MAP of >20 mm Hg from the patient's baseline value
- Anoxia of nonvital organs
- Hypoxia of vital organs
- Overall metabolism is anaerobic
 - Moderate acidosis
 - Moderate hyperkalemia
 - Tissue ischemia

Refractory Stage

- Severe tissue hypoxia with ischemia and necrosis
- Release of myocardial depressant factor from the pancreas
- Buildup of toxic metabolites
- Multiple organ dysfunction syndrome (MODS)
- Death

imbalances, and increased metabolites cause so much cell damage in vital organs that multiple organ dysfunction syndrome (MODS) occurs and recovery from shock is no longer possible. Table 39-2 summarizes the responses during the progression of shock.

Stages of Shock

The syndrome of shock progresses in four stages when the conditions that cause shock remain uncorrected and poor cellular oxygenation continues. These stages are:

1. Initial stage
2. Nonprogressive stage
3. Progressive stage
4. Refractory stage

The stages are defined on the basis of how well compensatory mechanisms are working, the severity of the clinical manifestations, and whether tissue damage is reversible.

Initial Stage of Shock (Early Stage). The initial (early) stage of shock is present when the patient's baseline MAP is decreased by less than 10 mm Hg. During this stage, compensatory mechanisms are so effective at returning systolic pressure to normal that oxygenated blood flow to vital organs is maintained. The cellular change in this stage is increased anaerobic metabolism with production of lactic acid,

although overall metabolism is still aerobic. The compensation responses of vascular constriction and increased heart rate are effective, and both cardiac output and MAP are maintained within the normal range. Because vital organ function is not disrupted, the manifestations of shock are difficult to detect. *A heart and respiratory rate increased from the patient's baseline level or a slight increase in diastolic blood pressure may be the only objective manifestation of this early stage of shock.*

Nonprogressive Stage of Shock (Compensatory Stage).

The nonprogressive (compensatory) stage of shock occurs when MAP decreases by 10 to 15 mm Hg from baseline. Kidney and hormonal compensatory mechanisms are activated because cardiovascular responses alone are not enough to maintain MAP and supply oxygen to vital organs.

The kidneys and baroreceptors sense an ongoing decrease in MAP and trigger the release of renin, antidiuretic hormone (ADH), aldosterone, epinephrine, and norepinephrine to start kidney compensation. Renin, secreted by the kidney, causes decreased urine output, increased sodium reabsorption, and widespread blood vessel constriction (see Fig. 13-6 in Chapter 13). ADH increases water reabsorption in the kidney, further reducing urine output, and also causes blood vessel constriction in the skin and other less vital tissue areas. Together these actions compensate for shock by maintaining the fluid volume within the central blood vessels.

Tissue hypoxia occurs in nonvital organs (e.g., skin, GI tract) and in the kidney, but it is not great enough to cause permanent damage. Because some metabolism is anaerobic, acid-base and electrolyte changes occur in response to the buildup of metabolites. Changes include **acidosis** (low blood pH) and **hyperkalemia** (increased blood potassium level).

Manifestations of the nonprogressive stage of shock include both subjective and objective changes resulting from decreased tissue perfusion. Subjective changes include thirst and anxiety. Objective changes include restlessness, tachycardia, increased respiratory rate, decreased urine output, falling systolic blood pressure, rising diastolic blood pressure, narrowing pulse pressure, cool extremities, and a 2% to 5% decrease in oxygen saturation measured by pulse oximetry. *Comparing these changes with the values and manifestations obtained earlier is critical to identifying this stage of shock.*

If the patient is stable and compensatory mechanisms are supported by medical and nursing interventions, he or she can remain in this stage for hours without having permanent damage. *Stopping the conditions that started the shock at this stage and providing supportive interventions can prevent the shock from progressing.* The cellular effects of this stage are reversible when nurses recognize the problem and coordinate with the health care team to start appropriate interventions (Mattiace, 2008; Stricker, 2010).

Progressive Stage of Shock (Intermediate Stage). The progressive stage of shock occurs when there is a sustained decrease in MAP of more than 20 mm Hg from baseline. In this stage, compensatory mechanisms are functioning but can no longer deliver sufficient oxygen, even to vital organs. Vital organs develop hypoxia, and less vital organs become **anoxic** (no oxygen) and **ischemic** (cell dysfunction or death from lack of oxygen). As a result of poor oxygenation and a buildup of toxic metabolites, some tissues have severe cell damage and die.

Manifestations of the progressive stage of shock include a *worsening* of subjective and objective changes resulting from decreased tissue perfusion. *Continuous monitoring and comparison with earlier findings are critical to assess therapy effectiveness.* Subjective changes include severe thirst sensation and deeper anxiety. The patient may express a sense of “something bad” (impending doom) about to happen. He or she may seem confused. Objective changes are a rapid, weak pulse; low blood pressure; pallor to cyanosis of oral mucosa and nail beds; cool and moist skin; anuria; and a 5% to 20% decrease in oxygen saturation. Laboratory data at this stage may show a low blood pH, along with rising lactic acid and potassium levels.

The progressive stage of shock is a life-threatening emergency. Vital organs can tolerate this situation for only a short time before being damaged permanently. Immediate interventions are needed to reverse the effects of this stage of shock. Tolerance varies from person to person and depends on age and health. The patient's life usually can be saved if the conditions causing shock are corrected within 1 hour or less of the onset of the progressive stage.

Refractory Stage of Shock (Irreversible Stage). The refractory stage or irreversible stage of shock occurs when too much cell death and tissue damage result from too little oxygen reaching the tissues. Vital organs have overwhelming damage. The body can no longer respond effectively to interventions, and shock continues. *Therapy is not effective in saving the patient's life, even if the cause of shock is corrected and MAP temporarily returns to normal.* So much tissue damage has occurred with widespread release of toxic metabolites and enzymes that cell damage in vital organs continues despite aggressive interventions. Manifestations are a rapid loss of consciousness; nonpalpable pulse; cold, dusky extremities; slow, shallow respirations; and unmeasurable oxygen saturation.

Multiple Organ Dysfunction Syndrome. The sequence of cell damage caused by the massive release of toxic metabolites and enzymes is termed **multiple organ dysfunction syndrome (MODS)**. Once the damage has started, the sequence becomes a vicious cycle as more dead cells break open and release harmful metabolites. These trigger small clots (*microthrombi*) to form, which block tissue oxygenation and damage more cells, thus continuing the devastating cycle. Liver, heart, brain, and kidney functions are lost first. The most profound change is damage to the heart muscle. One cause of this damage is the release of myocardial depressant factor (MDF) from the ischemic pancreas.

Etiology

Hypovolemic shock occurs when too little circulating blood volume causes a MAP decrease that prevents total body oxygenation. Common problems leading to hypovolemic shock are hemorrhage (external or internal) and dehydration.

Hypovolemic shock from external hemorrhage is common after trauma and surgery. Hypovolemic shock from internal hemorrhage occurs with blunt trauma, GI ulcers, and poor control of surgical bleeding. Hemorrhage also can be caused by any problem that reduces the levels of clotting factors (see Table 39-1). Hypovolemia as a result of dehydration can be caused by any problem that decreases fluid intake or increases fluid loss (see Table 39-1).

Incidence/Prevalence

The exact incidence of hypovolemic shock is not known because it is a response rather than a disease. It is a common complication among hospitalized patients in emergency departments and after surgery or invasive procedures.

Health Promotion and Maintenance

Hypovolemic shock from most causes can be prevented. Teach all people to prevent dehydration by having an adequate fluid intake during exercise and when in hot, dry environments. Urge people to prevent trauma and hemorrhage by using proper safety equipment and seat belts and being aware of hazards in the home or workplace.

Secondary prevention of hypovolemic shock is a major nursing responsibility. Keep in mind that just being a patient in the acute care setting is a risk factor. Identify patients at risk for dehydration, and assess for early manifestations. This is especially important for those who have reduced cognition or reduced mobility or who are on NPO status.

Assess all patients who have invasive procedures or trauma for obvious or occult bleeding. Compare pulse quality and rate with baseline. Compare urine output with fluid intake. Check vital signs for patients who have persistent thirst. Assess for shock in any patient who develops a change in mental status, an increase in pain, or an increase in anxiety.

When patients have invasive procedures or ambulatory surgery and then go home, teach them and their families the manifestations of shock. Stress the importance of seeking immediate help for obvious heavy bleeding, persistent thirst, decreased urine output, light-headedness, or a sense of impending doom (a feeling that something bad is happening or going to happen).

PATIENT-CENTERED COLLABORATIVE CARE

The Concept Map on p. 815 addresses assessment and nursing care issues related to hypovolemic shock.

ASSESSMENT

History

Ask about risk factors related to hypovolemic shock. If the patient is alert and stable, question him or her directly. If the patient is not alert or is not stable, collect information from family members. Age is important because hypovolemic shock from trauma is more common in young adults and other types of shock are more common in older adults. Ask patients about recent illness, trauma, procedures, or chronic health problems that may lead to shock. These problems include GI ulcers, general surgery, hemophilia, liver disorders, and prolonged vomiting and diarrhea. Ask about the use of drugs such as aspirin, other NSAIDs, and diuretics that may cause changes leading to hypovolemic shock.

Ask about fluid intake and output during the previous 24 hours. *Information about urine output is especially important because urine output is reduced during the first stages of shock, even when fluid intake is normal.*

Assess the patient for obvious signs or factors that can lead to shock. Areas to examine for signs of hemorrhage include the gums, wounds, and sites of dressings, drains, and vascular

Concept Map: Hypovolemic Shock

HISTORY

A 59-year-old involved in a motor vehicle crash comes to the ED confused and restless. Vitals are HR 120 (weak and thready), RR 24, BP 108/86 mm Hg. There are no open wounds, the abdomen is distended, and there are hypoactive bowel sounds.

Planning

EXPECTED OUTCOMES

- Clear thought processes
- MAP <10 mm Hg from baseline
- BP, HR, RR, ABGs, O₂ sat return to baseline
- U/O significantly >30 mL/hr
- No development of complications

Physical Assessment/
Clinical Manifestations
of Shock

Subjective signs:

Thirst, anxiety

Objective signs:

Restlessness; rapid, weak pulse; ↑ RR;
↓ U/O; ↓ systolic, ↑ diastolic BP (narrowing pulse pressure); cool extremities; ↓ O₂ sat; pallor, cyanosis; ↓ pH, ↑ lactic acid, ↑ K⁺

Causes

- Hemorrhage after blunt trauma
- Hemorrhage that reduces levels of clotting factors

Assess parameters at least every 15 minutes until shock is controlled and patient's condition improves

INTERVENTIONS

1	Patent Airway Administer O ₂ ; monitor and respond to ↑ RR, shallow depth; ↓ PaO ₂ ; cyanosis, especially around lips and nail beds. <i>Monitors for progression of shock.</i>
2	Nursing Safety Priority: Critical Rescue! Do not leave the patient. RN rather than LPN or UAP should assess vital signs. <i>An unstable patient requires the assessment skills of an RN.</i>
3	Physical Assessment Ensure vital sign readings are accurate; monitor for trends. Validate electronic readings with manual readings. <i>Ensures accuracy of measurement and assesses effectiveness of treatment.</i>
4	Nursing Safety Priority: Critical Rescue! Assess pulse rate and quality. Use changes in pulse as main indicators of shock. ↑ HR is earliest manifestation of shock. Peripheral pulses may be absent with progression. <i>Changes in systolic BP are not always present in the initial stage of shock.</i>
5	Bleeding Examine the patient for overt bleeding; apply direct pressure. Check under the patient for blood. Observe for swelling or skin discoloration. <i>Saves the patient's life if conditions are corrected within 1 hour of onset. Swelling or discoloration may indicate internal hemorrhage.</i>
6	Blood Pressure Monitor BP closely; elevate the patient's feet, keeping the head flat or elevated to a 30-degree angle. <i>Increases perfusion to the brain.</i>
7	Psychosocial Factors Reassure the patient in shock that the appropriate interventions are being implemented. <i>Calms the patient.</i>
8	Fluid Resuscitation Start an IV catheter or maintain an established catheter; ↑ the rate of IV fluid delivery. Prepare to give blood replacement therapy for hemorrhage using NS to prep an IV line. <i>Provides fluids, RBCs, clotting factors, and platelets to maintain perfusion to vital organs.</i>
9	Nursing Safety Priority: Drug Alert! Monitor the patient closely when giving drugs. ↑ CO and restore volume. <i>Monitors for systemic vasodilation and ↑ shock caused by drugs if patient is volume depleted.</i>
10	Surgery Preparation Prepare the patient for surgery. <i>Corrects internal bleeding for the patient's survival.</i>
11	Health Promotion & Safety Encourage proper use of safety equipment and seat belts, as well as awareness of hazards in the home or workplace. <i>Prevents trauma and hemorrhage, which is essential in health promotion teaching.</i>

Concept Map by Deanne A. Blach, MSN, RN

accesses. Also check *under* the patient for blood. Observe for any swelling or skin discoloration that may indicate an internal hemorrhage.

Physical Assessment/Clinical Manifestations

Most manifestations of hypovolemic shock are caused by the changes resulting from compensatory efforts. **Compensatory mechanisms** are physiologic responses that try to keep an adequate blood flow to vital organs. Signs of shock are first evident as changes in cardiovascular function. As shock progresses, changes in the renal, respiratory, integumentary, musculoskeletal, and central nervous systems become evident. Ensure that vital sign measurements are accurate, and monitor them for trends indicating shock.

! NURSING SAFETY PRIORITY

Action Alert

Assign a registered nurse rather than a licensed practical nurse/ licensed vocational nurse (LPN/LVN) or unlicensed assistive personnel (UAP) to assess the vital signs of a patient who is at risk for or suspected of having hypovolemic shock.

Cardiovascular changes that occur with hypovolemic shock start with decreased mean arterial pressure (MAP) leading to compensatory responses. Thus the earliest clinical signs of hypovolemic shock are cardiovascular.

Assess the central and peripheral pulses for rate and quality. In the initial stage of hypovolemic shock, the pulse rate increases to keep cardiac output and MAP at normal levels, even though the actual **stroke volume** (amount of blood pumped out from the heart) per beat is decreased. *Increased heart rate is the earliest manifestation of shock.* Because stroke volume is decreased, the peripheral pulses are difficult to palpate and are blocked with light pressure. As shock progresses, peripheral pulses may be absent.

When assessing the blood pressure of a patient at risk for shock, consider his or her normal baseline blood pressure. Although a blood pressure of 90/50 mm Hg may indicate severe shock in one person, it may be the normal blood pressure for another healthy adult.

! NURSING SAFETY PRIORITY

Action Alert

Because changes in systolic blood pressure are not always present in the initial stage of shock, use changes in pulse rate and quality as the main indicators of shock presence or progression.

With vasoconstriction, diastolic pressure increases but systolic pressure remains the same. As a result, the **pulse pressure**, which is the difference between the systolic and diastolic pressures, is smaller (also called “narrower”). Monitor blood pressure for changes from baseline levels and for changes from the previous measurement. For accuracy, use the same equipment on the same extremity. Validate an electronic reading with a manual reading.

Systolic pressure decreases as shock progresses and cardiac output decreases. A reduced systolic pressure narrows the pulse pressure even further. When shock continues and

interventions are not adequate, compensation fails and both systolic and diastolic pressures decrease. At this stage, blood pressure is difficult to hear. Palpation or a Doppler device may be needed to detect the systolic blood pressure.

Oxygen saturation is assessed through pulse oximetry. Pulse oximetry values between 90% and 95% occur with the nonprogressive stage of shock, and values between 75% and 80% occur with the progressive stage of shock. *Any value below 70% is considered a life-threatening emergency and may signal the refractory stage of shock.*

Respiratory changes with shock are an adaptive or compensatory response to help maintain oxygenation when tissue perfusion is decreased. Assess the rate, depth, and ease of respiration. Respiratory rate increases during hypovolemic shock to ensure that oxygen intake is increased so that it can be delivered to critical tissues. When shock progresses to the stage at which lactic acidosis is present, the respiratory depth also increases.

Kidney and urinary changes occur with shock to compensate for decreased MAP by saving body water through decreased filtration and increased water reabsorption. Assess urine for volume, color, specific gravity, and the presence of blood or protein. *Decreased urine output is a sensitive indicator of early shock. Measure urine output at least every hour. In severe shock, urine output may be absent.* Of the four vital organs (heart, brain, liver, and kidney), only the kidney can tolerate hypoxia and anoxia for up to 1 hour without permanent damage. When hypoxia or anoxia persists beyond this time, patients are at risk for acute kidney injury (AKI) and kidney failure.

Skin changes occur because of reduced blood flow in the skin. An early compensatory mechanism is skin blood vessel constriction, which reduces skin perfusion. This allows more blood to circulate to the vital organs, which cannot tolerate low oxygen levels.

Assess the skin for temperature, color, and moisture. With shock, it feels cool or cold to the touch and is moist. Color changes appear first in oral mucous membranes and in the skin around the mouth. Pallor or cyanosis is best assessed in the oral mucous membranes in dark-skinned patients. Other color changes are noted first in the skin of the extremities and then in the central trunk area. The skin feels clammy or moist to the touch, not because sweating increases but because the normal fluid lost through the skin does not evaporate well on cold skin. As shock progresses, skin becomes mottled. Lighter-skinned patients have an overall grayish blue color and darker-skinned patients appear darker, without an underlying reddish glow.

Evaluate capillary refill time by pressing on the patient's fingernail until it blanches and then observing how fast the nail bed resumes color when pressure is released. Normally these capillaries resume color as soon as pressure is released. With shock, capillary refill is slow or is sometimes absent. Capillary refill may not be a reliable indicator for peripheral blood flow in older patients or those with anemia, diabetes, or peripheral vascular disease.

Central nervous system changes with shock first manifest as thirst. Thirst is caused by stimulation of the thirst centers in the brain in response to decreased blood volume.

Assess the patient's level of consciousness (LOC) and orientation. Central nervous system changes of hypovolemic shock are caused by cerebral hypoxia. In the initial and

nonprogressive stages, patients may be restless or agitated and may be anxious or have a feeling of impending doom that has no obvious cause. As hypoxia progresses, confusion and lethargy occur. Lethargy progresses to somnolence and loss of consciousness as cerebral hypoxia worsens with shock progression.

Skeletal muscle changes during shock are muscle weakness and pain in response to tissue hypoxia and anaerobic metabolism, which are later manifestations. Weakness is generalized and has no specific pattern. The electrolyte changes of shock worsen muscle weakness by decreasing action potentials. Then deep tendon reflexes are decreased or absent.

Assess muscle strength by having the patient squeeze your hand and by trying to keep his or her arms flexed while you attempt to straighten them. Assess deep tendon reflexes by lightly tapping the patellar tendons and Achilles tendons with a reflex hammer and observing the degree of reflexive movement.

Psychosocial Assessment

Changes in mental status and behavior may be early signs of shock. Observe the patient closely, and document behavior. Assess mental status by evaluating LOC and noting whether the patient is asleep or awake. If the patient is asleep, attempt to awaken him or her and document how easily he or she is aroused. If the patient is awake, determine whether he or she is oriented to person, place, and time. Avoid asking questions that can be answered with a “yes” or a “no” response. Consider these points during assessment:

- Is it necessary to repeat questions to obtain a response?
- Does the response answer the question asked?
- Does the patient have difficulty making word choices?
- Is the patient irritated or upset by the questions?
- Can the patient concentrate on a question long enough to answer appropriately, or is the attention span limited?

If possible, talk with family members to determine whether the patient’s behavior and mental status are typical or represent a change.

Laboratory Assessment

Although no single laboratory finding confirms or rules out shock, changes in laboratory data may support the diagnosis. (Chart 39-2 lists laboratory changes occurring with hypovolemic shock.) As shock progresses, arterial blood gas values become abnormal. The pH decreases, the partial pressure of arterial oxygen (PaO_2) decreases, and the partial pressure of arterial carbon dioxide (PaCO_2) increases. Changes in other laboratory values may occur with specific causes of hypovolemic shock.

Hematocrit and hemoglobin levels decrease if shock is caused by hemorrhage. When shock is caused by dehydration or a fluid shift, hematocrit and hemoglobin levels are elevated.

ANALYSIS

The priority problems for patients with hypovolemic shock are:

1. Hypoxia related to hypovolemia
2. Hypoperfusion related to active fluid volume loss and hypotension

CHART 39-2 LABORATORY PROFILE

Hypovolemic Shock

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
pH (arterial)	7.35-7.45	Decreased: insufficient tissue oxygenation causing anaerobic metabolism and acidosis
PaO_2	80-100 mm Hg	Decreased: anaerobic metabolism
PaCO_2	35-45 mm Hg	Increased: anaerobic metabolism
Lactic acid (arterial)	3-7 mg/dL 0.3-0.8 mmol/L	Increased: anaerobic metabolism with buildup of metabolites
Hematocrit	Females: 37%-47% Males: 42%-52%	Increased: fluid shift, dehydration Decreased: hemorrhage
Hemoglobin	Females: 12-16 g/dL Males: 14-18 g/dL	Increased: fluid shift, dehydration Decreased: hemorrhage
Potassium	3.5-5.0 mEq/L or mmol/L	Increased: dehydration, acidosis

Data from Pagana, K., & Pagana, T. (2010). *Mosby's manual of diagnostic and laboratory tests* (4th ed.). St. Louis: Mosby.

PaCO_2 , Partial pressure of arterial carbon dioxide; PaO_2 , partial pressure of arterial oxygen.

3. Anxiety related to potential for death and decreased cerebral perfusion
4. Confusion related to decreased cerebral perfusion

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Safety

A 30-year-old man comes to the emergency department because of increasing pain in the left upper abdominal quadrant. Several hours ago, he was hit hard in that area during a tackle by the head of a football player who was wearing a helmet. He has no other health problems, and the only drug he takes on a regular basis is 325 mg of aspirin daily. These are his vital signs: pulse, 102; respirations, 22; blood pressure, 110/86; oxygen saturation, 96%. He has not eaten since he was hit but did drink a bottle of water on the way to the hospital because he was thirsty. When you examine his abdomen, bruising is present in the left upper quadrant and extends down his left side.

1. Where else should you look for evidence of bleeding?
2. What manifestations of shock are present?
3. How would you classify this stage of shock? Provide a rationale for your evaluation.
4. What additional information should you obtain?
5. What vital sign(s) should you monitor most closely?

INTERVENTIONS

Medical and nursing interventions for patients in hypovolemic shock focus on reversing the shock, restoring fluid volume to the normal range, and preventing complications through supportive and drug therapies. Monitoring is critical to determine whether the patient is responding to therapy or whether shock is progressing and a change in intervention is

CHART 39-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient in Hypovolemic Shock

- Ensure a patent airway.
- Start an IV catheter, or maintain an established catheter.
- Administer oxygen.
- Elevate the patient's feet, keeping his or her head flat or elevated to no more than a 30-degree angle.
- Examine the patient for overt bleeding.
- If overt bleeding is present, apply direct pressure to the site.
- Administer drugs as prescribed.
- Increase the rate of IV fluid delivery.
- Do not leave the patient.

needed. Surgery may be needed to correct the cause of shock. [Chart 39-3](#) lists best practices for patients in hypovolemic shock.

Nonsurgical Management

The purposes of shock management are to maintain tissue oxygenation, increase vascular volume to normal range, and support compensatory mechanisms. Oxygen therapy, fluid replacement therapy, and drug therapy are useful for this problem.

Oxygen therapy is for any stage of shock and is delivered by mask, hood, nasal cannula, nasopharyngeal tube, endotracheal tube, or tracheostomy tube. It is given in liters per minute (L/min) (when using a cannula) or concentration by percentage (when using a mask).

IV therapy for fluid resuscitation is a primary intervention for hypovolemic shock. Crystalloids and colloids are the fluid types used for volume replacement. Crystalloid solutions contain nonprotein substances (e.g., minerals, salts, sugars). Colloid solutions contain large molecules (usually proteins or starches) (see [Chapter 13](#)).

Crystalloid fluids are given to help maintain an adequate fluid and electrolyte balance. Two common solutions are normal saline and Ringer's lactate. Normal saline (0.9% sodium chloride in water) is the fluid replacement solution of choice used to increase plasma volume and can be infused with any blood product. Ringer's lactate contains sodium, chloride, calcium, potassium, and lactate dissolved in water. This isotonic solution expands volume, and the lactate buffers acidosis.

! NURSING SAFETY PRIORITY

Action Alert

Use only normal saline for infusion with blood or blood products because the calcium in Ringer's lactate induces clotting of the infusing blood.

Protein-containing colloid fluids help restore osmotic pressure and fluid volume. Blood and blood products are often used for this purpose when shock is caused by blood loss. These fluids include whole blood, packed red blood cells, plasma, and synthetic plasma expanders.

Whole blood and packed red blood cells increase hematocrit and hemoglobin levels along with fluid volume. Whole

blood is used to replace large blood losses because it increases volume and improves the oxygen-carrying capacity of the blood. Packed red cells are given for moderate blood loss because they restore the red blood cell deficit and improve oxygen-carrying capacity without adding excessive fluid volume. [Chapter 42](#) discusses nursing care issues when giving blood or blood products.

Plasma, an acellular blood product containing clotting factors, is given to restore osmotic pressure when hematocrit and hemoglobin levels are within normal ranges. Plasma protein fractions (e.g., Plasmanate) and synthetic plasma expanders (e.g., hetastarch [hydroxyethyl starch, Hespan]) increase volume and are used for hypovolemic shock before a cause is identified.

Drug therapy is used when the volume lost is severe and the patient does not respond sufficiently to fluid replacement and blood products. The actions of drugs for shock increase venous return, improve cardiac contractility, or improve cardiac perfusion by dilating the coronary vessels ([Cooper, 2008](#)). [Chart 39-4](#) lists the drugs used to treat hypovolemic shock.

Vasoconstricting drugs stimulate venous return by constricting blood vessels and decreasing venous pooling. These actions increase cardiac output and mean arterial pressure (MAP), which help improve perfusion and oxygenation. Such agents include dopamine (Intropin, Revimine ) and norepinephrine (Levophed). These drugs can produce serious side effects, and their dosages must be carefully calculated on the basis of the patient's size and response to treatment ([Cooper, 2008](#)) (see [Chart 39-4](#)).

Inotropic drugs stimulate adrenergic receptors in the heart (beta₁ receptors) and improve heart muscle cell contraction. Thus greater recoil occurs and more blood leaves the left ventricle during contraction. These drugs include dobutamine (Dobutrex) and milrinone (Primacor).

Drugs enhancing myocardial perfusion help ensure that the heart is well perfused, especially when giving drugs to improve cardiac contraction, so that aerobic metabolism is maintained in the heart cells and maximum contractility can occur. Drugs that dilate coronary blood vessels while minimally dilating systemic vessels are used for this purpose. A common drug with this action is sodium nitroprusside (Nitropress, Nipride .

! NURSING SAFETY PRIORITY

Drug Alert

Monitor the patient closely because drugs that dilate coronary blood vessels, such as nitroprusside, can cause systemic vasodilation and increase shock if the patient is volume depleted.

Monitoring vital signs and level of consciousness is a major nursing action to determine the patient's condition and the effectiveness of therapy. Monitor these vital signs:

- Pulse
- Blood pressure
- Pulse pressure
- Central venous pressure (CVP)
- Respiratory rate
- Skin and mucosal color

CHART 39-4 COMMON EXAMPLES OF DRUG THERAPY

Hypovolemic Shock

DRUG/USUAL DOSAGE	PURPOSE/ACTION	NURSING INTERVENTIONS	RATIONALES
Vasoconstrictors			
Dopamine (Intropin, Revimine 🍁) 5-20 mcg/kg/min IV	Improve blood flow by increasing peripheral resistance, increasing venous return to the heart, and improving myocardial contractility.	Assess the patient for chest pain.	Drug increases myocardial oxygen consumption.
Norepinephrine (Levophed), initial dose 0.5-1 mcg/min IV, to maintain systolic BP between 90 and 100 mm Hg		Monitor urine output hourly.	Higher doses decrease renal perfusion and urine output.
Phenylephrine HCl 0.1-0.5 mg IV every 15 min		Assess blood pressure every 15 min.	Hypertension is a sign of overdose.
		Assess the patient for headache.	Headache is an early symptom of drug excess.
		Assess every 30 min for extravasation, and check extremities for color and perfusion.	If the drug gets into the tissues, it can cause severe vasoconstriction, tissue ischemia, and tissue necrosis.
		Assess for chest pain.	Drug can cause rapid onset of vasoconstriction in the myocardium and impair cardiac oxygenation.
Inotropic Agents			
Dobutamine (Dobutrex) 1.0-20 mcg/kg/min IV as a continuous infusion	Directly stimulate adrenergic receptor sites on the heart muscle (beta ₁ receptors) and improve heart muscle cell contraction.	Assess for chest pain.	Drug increases myocardial oxygen consumption and can cause angina or infarction.
Milrinone (Primacor) 50 mcg/kg bolus over 10 min; 0.3-0.75 mcg/kg/min continuous IV infusion		Assess blood pressure every 15 min.	Hypertension is a sign of overdose.
Agents Enhancing Myocardial Perfusion			
Sodium nitroprusside (Nitropress, Nipride 🍁) 0.25-10 mcg/kg/min IV	Improves blood flow to the myocardium by dilating the coronary arteries. This effect is primary and rapid but short.	Protect drug container from light. Assess blood pressure at least every 15 min.	Light degrades drug quickly. The vasodilating effect can cause systemic vasodilation and hypotension, especially in older adults.

- Oxygen saturation
- Mental status
- Urine output

Assess these parameters at least every 15 minutes until the shock is controlled and the patient's condition improves. Hemodynamic monitoring in critical care settings includes intra-arterial monitoring, mixed venous oxygen saturation (SvO₂), pulmonary artery monitoring, and pulmonary capillary wedge pressures.

Insertion of a CVP catheter allows pressure to be monitored in the patient's right atrium or superior vena cava while providing venous access. A decrease of CVP from baseline levels reflects hypovolemic shock with reduced venous return to the right atrium.

Intra-arterial catheters allow continuous blood pressure monitoring and are an access for arterial blood sampling. They are inserted into an artery (radial, brachial, femoral, or dorsalis pedis). The catheter is attached to pressure tubing and a transducer, which converts arterial pressure into an electrical signal seen as a waveform on an oscilloscope and as a digital numeric value.

Surgical Management

The nonsurgical interventions described on pp. 818 and 819 are used to stabilize the patient's hemodynamic status. Surgical intervention may be needed to correct the cause of shock. Such procedures include vascular repair, surgical hemostasis of major wounds, closure of bleeding ulcers, and chemical scarring (chemosclerosis) of varicosities.

Community-Based Care

Hypovolemic shock is a complication of another condition and is resolved before patients are discharged from the acute care setting. Because more patients are having surgery and other invasive procedures on an outpatient basis, more patients at home are at increased risk for hypovolemic shock. Teach patients and family members the early manifestations of shock (increased thirst, decreased urine output, lightheadedness, sense of apprehension) and to seek immediate medical attention if they appear.

**NCLEX EXAMINATION CHALLENGE****Safe and Effective Care Environment**

Which vital sign change in a client with hypovolemic shock indicates to the nurse that the therapy is effective?

- Urine output increase from 5 mL/hr to 25 mL/hr
- Pulse pressure decrease from 35 mm Hg to 28 mm Hg
- Respiratory rate increase from 22 breaths/min to 26 breaths/min
- Core body temperature increase from 98.2° F (36.8° C) to 98.8° F (37.1° C)

SEPSIS AND SEPTIC SHOCK**Pathophysiology**

Sepsis and septic shock is a complex type of distributive shock that usually begins as a bacterial or fungal infection and progresses to a dangerous condition over a period of days. The

FIG. 39-3 Common progression of events leading to septic shock.

progression of septic shock is outlined in Fig. 39-3. As progression occurs, the pathologic problems occur faster and to a greater degree. Thus control of sepsis and prevention of severe sepsis and septic shock through appropriate intervention are easier to achieve early in the course of the problem. Failure to recognize and intervene in early sepsis is the major contributing factor for progression to septic shock and death (Dodge, 2010; Nelson et al., 2009).

Infection

When infection is confined to a local area, it should not lead to sepsis and shock. In the person whose immune system and inflammatory responses are effective, the presence of organism invasion first starts a helpful, nonspecific series of local responses to confine and eliminate the organism and to prevent the infection from becoming worse or widespread.

The white blood cells (WBCs) in the area of invasion secrete cytokines to trigger a local inflammatory response and bring more WBCs to fight and kill the invading organisms. The results of this local response constrict the small veins and dilate the arterioles in the area. These blood vessel changes increase blood flow to locally infected tissues and deliver more nutrients.

Capillary leak also occurs, allowing blood plasma to leak into the tissues. This response causes swelling and dilutes any microorganisms and their toxins that have entered the area. The duration of these responses depends on the size and severity of the infection, but usually they subside within a few days, when the infection has been managed by these responses. A benefit of these responses is that they are limited only to the area of infection and stop as soon as they are no longer needed. The patient does not have fever, tachycardia, decreased oxygen saturation, or reduced urine output.

Sepsis and Systemic Inflammatory Response Syndrome

Sepsis is a condition in which infectious microorganisms have entered the bloodstream. As the numbers of organisms increase, an inflammatory response, known as *systemic inflammatory response syndrome (SIRS)*, is triggered as a result of infection escaping local control. With the organisms and their toxins in the bloodstream at this point and entering other body areas, the inflammatory responses become an enemy, leading to extensive hormonal, tissue, and vascular changes and oxidative stress that further impair oxygenation and tissue perfusion (Landis, 2009). The WBCs are producing many pro-inflammatory cytokines, especially interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor—alpha (TNF-A or TNF- α) (Abbas et al., 2010). (See Chapter 19 for a discussion of cytokines.) As a result, there is widespread vasodilation and blood pooling. The patient has mild hypotension, a low urine output, and an increased respiratory rate. These responses result in a hypodynamic state with decreased cardiac output. Body temperature varies depending on the duration of the sepsis and on WBC function. Some patients have a low-grade fever and others have a high fever. Still others may have a below-normal body temperature. Fever and hypotension result directly from SIRS. The reduced urine output and increased respiratory rate are the compensatory responses to impaired oxygenation and tissue perfusion. Usually in this stage, the patient has the elevated WBC count expected with a systemic infection.

Microthrombi begin to form in some organ capillaries, causing hypoxia and reducing organ function. This problem is hard to detect, but if sepsis is stopped at this point, the organ damage is completely reversible. The microthrombi increase hypoxic conditions, which then generate more toxic metabolites. These damage more cells and increase the production of pro-inflammatory cytokines, leading to an amplification of SIRS and a vicious repeating cycle of poor oxygenation and tissue perfusion (Fig. 39-4). Although these manifestations are subtle, they indicate sepsis and SIRS and will progress unless intervention begins now.

Unfortunately, this early hypodynamic state has a relatively short duration and manifestations are so subtle that the condition is often missed or misdiagnosed. When early sepsis and SIRS are identified and treated aggressively at this stage, the cycle of progression is stopped and the outcome is good. When sepsis and SIRS are not identified and treated at this stage, it almost always progresses to severe sepsis, which is much harder to control. Nurses, as well as all other health care professionals, have a responsibility to identify cues that indicate sepsis before it becomes severe. Identifying criteria have been established (Table 39-3) and must be used to ensure interventions are instituted at this stage (Giuliano, Lecardo, & Staul, 2011).

! NURSING SAFETY PRIORITY

Critical Rescue

Notify the health care provider or the Rapid Response Team for any patient who has vital signs or other conditions that meet the sepsis with SIRS criteria.

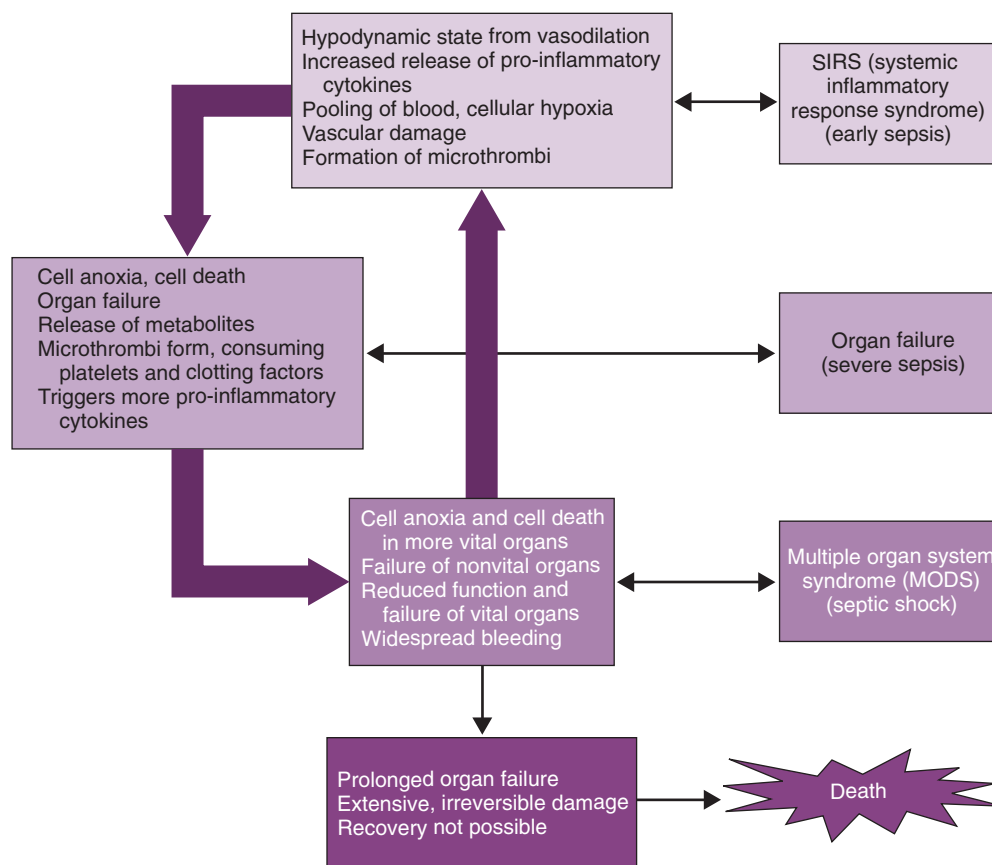

FIG. 39-4 Vicious cycle of systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS) in septic shock.

TABLE 39-3 SEPSIS WITH SYSTEMIC INFLAMMATORY RESPONSE SYNDROME (SIRS) CRITERIA

- Temperature of more than 100.4° F (38° C) or less than 96.8° F (36° C)
- Heart rate of more than 90 beats per minute
- Respiratory rate of more than 20 breaths per minute or a PaCO₂ level of less than 32 mm Hg
- Abnormal white blood cell count (>12,000/mm³ or <4000/mm³ or >10% segs or >10% bands)
- Sepsis is considered to be present if two or more SIRS criteria are present along with any known infection and one or more of these clinical manifestations:
 - Hypotension
 - Urine output less than expected for fluid intake
 - Positive fluid balance
 - Decreased capillary refill
 - Hyperglycemia (>120 mg/dL in the absence of known diabetes)
 - Unexplained change in mental status
 - Rising serum creatinine level in a person with no known history of kidney problems (>2.0 mg/dL [men], >1.4 mg/dL [women])

Modified from American College of Chest Physicians (ACCP) and the Society of Critical Care Medicine (SCCM).

PaCO₂, Partial pressure of arterial carbon dioxide.

Severe Sepsis

Severe sepsis is the progression of sepsis with an amplified inflammatory response (see Fig. 39-4). All tissues are involved and are hypoxic to some degree. Some organs are experiencing cell death and dysfunction at this time. Microthrombi formation is widespread, using much of the available platelets and clotting factors, a condition known as *disseminated intravascular coagulation (DIC)*. The amplified SIRS and cytokine release increase capillary leakiness, injure cells, and increase cell metabolism. Damage to endothelial cells reduces anticoagulating actions and triggers the formation of even more small clots. Anaerobic metabolism continues, and cell uptake of oxygen is poor. The continued stress response triggers the continued release of glucose from the liver and causes hyperglycemia. The more severe the response, the higher the blood glucose level.

Despite the severity of this stage and the fact that it may be present for 24 hours or more, it is often missed. One of the reasons it may be missed is that the cardiac function is hyperdynamic in this phase. The pooling of blood and the widespread capillary leak stimulate the heart, and cardiac output is *increased* with a more rapid heart rate and an elevated systolic blood pressure. In addition, the patient's extremities may feel warm and there is little or no cyanosis. Even though the patient may "look" better, the pathologic changes occurring at the tissue level are serious and have caused significant damage. The WBC count at this time may no longer be elevated. The reason for this is that a prolonged

TABLE 39-4 CONDITIONS PREDISPOSING TO SEPSIS AND SEPTIC SHOCK

- Malnutrition
- Immunosuppression
- Large, open wounds
- Mucous membrane fissures in prolonged contact with bloody or drainage-soaked packing
- GI ischemia
- Exposure to invasive procedures
- Malignancy
- Older than 80 years
- Infection with resistant microorganisms
- Receiving cancer chemotherapy
- Alcoholism
- Diabetes mellitus
- Chronic kidney disease
- Transplantation recipient
- Hepatitis
- HIV/AIDS

AIDS, Acquired immune deficiency syndrome; HIV, human immune deficiency virus.

sepsis stage may have worn out the bone marrow's ability to keep producing and releasing new mature neutrophils and other WBCs. The WBC count may be extremely low, especially the segmented neutrophils (segs).

Clinical manifestations of this stage include a lower oxygen saturation, rapid respiratory rate, decreased to absent urine output, and a change in the patient's cognition and affect. Appropriate and aggressive interventions at this stage can still prevent septic shock, although mortality after a patient reaches this stage is much higher than for sepsis and SIRS. *At this point, the downhill course leading to septic shock is extremely rapid.*

Septic Shock

Septic shock is the stage of sepsis and SIRS when multiple organ failure is evident and uncontrolled bleeding occurs (see Fig. 39-4). *Even with appropriate intervention, the death rate among patients in this stage of sepsis exceeds 50% (Toussaint & Gerlach, 2009).* Severe hypovolemic shock and hypodynamic cardiac function are present as a result of an inability of the blood to clot because the platelets and clotting factors were consumed earlier. Capillary leak continues and cardiac contractility is poor from cellular ischemia. The clinical manifestations resemble the late stage of hypovolemic shock.

Etiology

The major cause of sepsis is a bacterial infection that escapes local control, although in immunocompromised patients, fungal infections also cause sepsis. Common organisms causing sepsis include gram-negative bacteria (*Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella pneumoniae*) and gram-positive bacteria (*Staphylococcus* and *Streptococcus*). Table 39-4 lists some of the health problems that increase the risk for sepsis and septic shock.

Incidence/Prevalence

Sepsis and septic shock are common events in the United States. More than 750,000 cases occur annually and result in over 200,000 deaths. Although sepsis management has improved, the incidence is increasing as a result of more

drug-resistant organisms and the fact that patients are discharged from the hospital "quicker and sicker." Sepsis takes time to develop, and the patient may be discharged before manifestations are obvious.

Health Promotion and Maintenance

Prevention is the best management strategy for sepsis and septic shock. Evaluate all patients for their risk for sepsis, especially older adults, because the death rate from sepsis in people older than 65 years is nearly twice that of younger adults (El Solh et al., 2008). Table 39-4 lists some of the health problems that increase the risk for septic shock. Use aseptic technique during invasive procedures and when working with nonintact skin and mucous membranes in immunocompromised patients. Remove indwelling urinary catheters and IV access lines as soon as they are no longer needed.

Early detection of sepsis before progression to septic shock is a major nursing responsibility. Because sepsis can be a complication of many conditions found in acute care settings, always consider its possibility. Assess vital signs often (at least twice per shift) for changes from baseline levels. Review laboratory data for changes in serum lactate levels, in total white blood cell (WBC) count, and in the differential. The hallmark of sepsis is an increasing serum lactate level, a normal or low total WBC count, and a decreasing segmented neutrophil level with a rising band neutrophil level. This change is called a **left shift** (see Chapter 19).

Early detection can be made by patients and families, as well as health care personnel. This is especially important for patients discharged to home after invasive procedures or surgery. Teach patients the manifestations of local infection (local redness, pain, swelling, purulent drainage, loss of function) and of early sepsis (fever, urine output less than intake, light-headedness). Teach them how to use a thermometer and to take the temperature twice a day and whenever they are not feeling well. Urge those with symptoms of early sepsis to immediately contact their health care provider. Teach them that if antibiotics are prescribed, to take these drugs as prescribed and to complete the entire course.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which newly admitted client does the nurse consider to be at highest risk for development of sepsis?

- A. 75-year-old man with hypertension and early Alzheimer's disease
- B. 68-year-old woman 2 days postoperative from bowel surgery
- C. 80-year-old community-dwelling man with no other health problems undergoing cataract surgery
- D. 54-year-old woman with moderate asthma and severe degenerative joint disease of the right knee

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Sepsis and septic shock differ from other types of shock in many ways. The entire syndrome may occur over many hours to days, and the manifestations are less obvious. The chance for recovery is good when the patient is recognized as having

TABLE 39-5 CHANGES IN SELECTED PARAMETERS DURING SEPSIS AND SEPTIC SHOCK

PARAMETER	NORMAL	EARLY SEPSIS	LATE SEPSIS	SEPTIC SHOCK
Cardiac output	Normal 3-5 L/min	Decreased	Increased	Greatly decreased
Stroke volume	Normal 60-80 mL	Decreased	Increased	Greatly decreased
Serum lactate (arterial)	<2 mmol/L	Normal to slightly increased	2-4 mmol/L	>4 mmol/L
Blood glucose	<110 mg/dL	110-120 mg/dL	120-150 mg/dL	>150 mg/dL
Oxygen saturation	95%-100%	<95%	<85%	<80%
Serum creatinine	0.6-1.2 mg/dL (men) 0.5-1.1 mg/dL (women)	Normal to slightly increased	>2.0 mg/dL (men) >1.4 mg/dL (women)	>3.0 mg/dL (either gender)
Segmented neutrophils	55%-70% of white blood cell count	Increased	Decreased	<10%
Band neutrophils	2%-5% of total white blood cell count	Normal to slightly increased	>10%	>20%

CHART 39-5 NURSING FOCUS ON THE OLDER ADULT

Risk Factors for Shock

Hypovolemic Shock

- Diuretic therapy
- Diminished thirst reflex
- Immobility
- Use of aspirin-containing products
- Use of complimentary therapies such as *Ginkgo biloba*
- Anticoagulant therapy

Cardiogenic Shock

- Diabetes mellitus
- Presence of cardiomyopathies

Distributive Shock

- Diminished immune response
- Reduced skin integrity
- Presence of cancer
- Peripheral neuropathy
- Strokes
- Institutionalization (hospital or extended-care facility)
- Malnutrition
- Anemia

Obstructive Shock

- Pulmonary hypertension
- Presence of cancer

sepsis with SIRS and appropriate interventions are started. Septic shock, on the other hand, has a rapid downhill course, and chances for recovery are relatively poor. Identifying patients in the earlier stages of sepsis can make the greatest difference in survival. Second, the cause of sepsis is often less obvious than for other types of shock.

History

Age is important because sepsis develops more easily among older, debilitated patients who are immunosuppressed (El Solh et al., 2008). [Chart 39-5](#) lists factors that increase the older adult's risk for shock. Ask about the patient's medical history, including recent illness, trauma, invasive procedures, or chronic conditions that may lead to sepsis. Check which drugs the patient has used in the past week. Some drugs may directly cause changes leading to shock. Also, a drug regimen may indicate a disease or problem that can contribute to sepsis. These drugs include aspirin and aspirin-containing drugs, antibiotics, and cancer therapy drugs.

Physical Assessment/Clinical Manifestations

Manifestations of sepsis and septic shock occur over many hours, and some change during the progression. [Table 39-5](#) summarizes specific manifestations and laboratory changes from normal during the different stages of sepsis and septic shock.

Cardiovascular changes differ in the different stages of sepsis and septic shock. Cardiac output and blood pressure are lower (hypodynamic) in early sepsis and in septic shock. In severe sepsis, cardiac output is higher as are heart rate and blood pressure (hyperdynamic), although this is an indication of a worsening condition rather than an improvement. Increased cardiac output is reflected by tachycardia, increased stroke volume, a normal systolic blood pressure, and a normal central venous pressure (CVP). Increased cardiac output and vasodilation make the skin color appear normal with pink mucous membranes, and the skin is warm to the touch. This situation is temporary, and eventually the cardiac output is greatly reduced.

With progression, disseminated intravascular coagulation (DIC) occurs with formation of thousands of small clots in the tiny capillaries of the liver, kidney, brain, spleen, and heart. DIC reduces oxygenation and decreases oxygen saturation, causing hypoxia and ischemia.

The huge number of small clots uses clotting factors and fibrinogen faster than they can be produced. This problem increases the risk for hemorrhage, which occurs in the septic shock stage. Coupled with the continued capillary leak, the bleeding causes hypovolemia and a dramatic decrease in cardiac output, blood pressure, and pulse pressure. The manifestations of this phase are the same as those of the later stages of hypovolemic shock.

Respiratory changes are first caused by compensatory mechanisms that try to maintain oxygenation with a rate increase. As tissue hypoxia becomes more profound and metabolic acidosis is present, the depth of respiration also increases. The lungs are susceptible to damage, and the complication of acute respiratory distress syndrome (ARDS) may occur in septic shock. ARDS in septic shock is caused by the continued systemic inflammatory response syndrome (SIRS) increasing the formation of oxygen free radicals, which damage lung cells. *ARDS in a patient with septic shock has a high mortality rate.*

Skin changes differ at different stages of sepsis. In the hypodynamic stages, blood is shunted away from the skin, and pallor, cyanosis, or mottling may be present. In the hyperdynamic stage, the skin is warm and no cyanosis is evident. With

progression to septic shock and compromised circulation, the skin is cool and clammy with pallor, mottling, or cyanosis. In patients with DIC, petechiae and ecchymoses can occur anywhere. Blood may ooze from the gums, other mucous membranes, and venipuncture sites, as well as around IV catheters.

A *kidney/urinary change* of low urine output compared with fluid intake indicates shock. When a patient who has no known kidney or bladder problem suddenly starts having a low urine output, be suspicious of severe sepsis or septic shock. Reduced output is caused by capillary leak, low circulating volume, and hormonal changes. Kidney function decreases, and serum creatinine levels increase.

Psychosocial Assessment

The indicator that patients may be in the beginning of severe sepsis is often a change in affect or behavior. Compare the patient's current behavior, verbal responses, and general affect with those assessed earlier in the day or the day before. They may seem just slightly different in their reactions to greetings, comments, or jokes. They may be less patient than usual or act restless or fidgety. Patients may make statements such as, "I feel as if something is wrong, but I don't know what." If behavior is changed from prior assessments, consider the possibility of severe sepsis and shock.

Laboratory Assessment

No single laboratory test confirms the presence of sepsis and septic shock. The presence of bacteria in the blood supports the diagnosis of sepsis although this finding may not be present. Obtain specimens of urine, blood, sputum, and any drainage for culture to identify the causative organisms. Other abnormal laboratory findings that occur with septic shock include changes in the white blood cell (WBC) count; the differential leukocyte count may show a left shift. Hematocrit and hemoglobin levels usually do not change until late in septic shock. At that point, the hematocrit and hemoglobin levels, fibrinogen levels, and platelet count are low from disseminated intravascular coagulation (DIC). The serum lactate level is above normal, and the serum bicarbonate levels are lower than normal. Unfortunately, these parameters may take time to change and cannot be relied on as sensitive indicators of the patient's worsening condition.

Another indicator of sepsis and septic shock is a low blood level of activated protein C. Protein C is an enzyme that prevents inappropriate clot formation. It is activated when it binds to healthy vascular endothelial cells. In severe sepsis, the injured endothelial cells cannot activate protein C and thousands of small clots form in the capillaries of vascular organs. Decreasing levels of activated protein C indicate the beginning of severe sepsis even before other manifestations are evident.

Other biologic indicators of severe sepsis and septic shock are changes in plasma D-dimer levels and specific cytokine (interleukin-6 [IL-6] and interleukin-10 [IL-10]) levels. Plasma D-dimer levels rise during sepsis as the fibrin in clots is broken down. IL-6 is a pro-inflammatory cytokine, and IL-10 is an anti-inflammatory cytokine. In sepsis, IL-6 levels rise and IL-10 levels either remain normal or decrease. These indicators have a lag time, and changes may not be present soon enough to identify sepsis with SIRS before severe sepsis or septic shock develops.

EVIDENCE-BASED PRACTICE

Watch the Procalcitonin Levels

Schuetz, P., Christ-Crain, M., & Müller, B. (2008). Procalcitonin and other biomarkers for the assessment of disease severity and guidance of treatment in bacterial infections. *Advances in Sepsis*, 6(3), 82-89.

Septic shock is a result of infection progression. The outcomes of severe sepsis and septic shock are poor, with a high rate of mortality. Ideally, sepsis should be managed in the early stages (systemic inflammatory response syndrome [SIRS]) before overwhelming bacterial toxin levels lead to multiple organ dysfunction syndrome. However, manifestations of sepsis with SIRS are often missed, leading to severe sepsis and rapid progression to septic shock, which may occur before the results of blood cultures (considered the "gold standard" for a sepsis diagnosis) are available. This study, through a systematic integrative review, examined the published evidence for 30 years regarding the use of surrogate biomarkers to identify the presence of sepsis and SIRS.

Although the levels of various cytokines and clotting degradation products change over the course of sepsis progression, these changes lag and are not sufficiently sensitive for rapid identification of increasing sepsis. In a variety of clinical and laboratory studies, procalcitonin (PCT) showed clear and consistent changes that correlated well with the level of blood contamination with microorganisms (a prerequisite for sepsis and sepsis progression) during a health problem with ambiguous presentation. PCT shows a rapid elevation at early stages of bloodstream infection and decreases nearly as rapidly as bloodstream infections clear, either as a result of immune function or as a result of antibiotic therapy. Changes in PCT levels are very sensitive in determining when to start antibiotic therapy, when to change or increase antibiotic therapy, and when antibiotic therapy can be safely discontinued.

Level of Evidence: 1

The clinical evidence presented was determined as a result of a systematic integrative review of the utility of biomarkers during the progression of infection, sepsis, systemic inflammatory response syndrome, severe sepsis, and septic shock. It also included results from large, well-controlled animal studies.

Commentary: Implications for Practice and Research

This study is critically important to providing an objective and sensitive measure of sepsis that can be used by all health care professionals to identify sepsis with SIRS at an earlier stage when recovery is more likely with appropriate intervention. Bedside nurses, who have the longest interactions with patients, are often the first to consider the possibility of sepsis from subtle changes in the patient's condition and demeanor. Having an objective test that supports assessment data can lead to better outcomes of sepsis management.

Because the results of blood cultures may not be available until the patient's condition has progressed to severe sepsis or septic shock, other biomarkers for sepsis and SIRS are needed to help identify the condition when it can be managed and cured. Many cytokine blood levels have been considered for this "surrogate" marker of sepsis; however, tests have not been sensitive enough to rely on these levels for diagnosis. Another promising biomarker is the blood procalcitonin (PCT) levels (Schuetz et al., 2008). Levels of this prohormone, which also is a mediator of responses to infection, increase whenever bacteria enter the bloodstream, and the level continues to rise as the blood bacterial concentration increases. The PCT levels drop as the bacterial levels decrease, making it an indicator of therapy effectiveness (see the Evidence-Based Practice box above).

The actual diagnosis of sepsis is difficult to make, yet the best outcome depends on an early diagnosis and the implementation of appropriate aggressive interventions. In general, sepsis is considered to exist when an infection is present along with any two of the established SIRS criteria, with any one of the additional clinical manifestations (see [Table 39-3](#)).

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is an 82-year-old woman who has been a resident in an extended-care facility for the past year because of poor mobility and self-care problems. Today she is brought to the emergency department because she does not recognize her son and does not know where she is. She completed drug therapy for a urinary tract infection 1 week ago. Her skin is thin, and she has many bruises. In addition, she has a healing wound on her left shin, which her son tells you occurred 3 days ago when she scraped the area trying to get out of bed alone. The skin immediately surrounding the wound appears normal; however, about 3 inches to the right of the wound the skin is red, firm, and warm to the touch. These are her vital signs: T, 100.8° F (38.2° C); P, 112 beats/min; R, 24 breaths/min; BP, 118/80; SpO₂, 92%. Oxygen at 3 L/min is applied until the neurologist can evaluate her, and an IV with normal saline is started at 100 mL/hr. Her son is concerned because she was given her oral antidiabetic drug this morning (5 hours ago) but has not eaten breakfast or lunch. When you check her blood glucose level, it is 131 mg/dL. When you assess her 15 minutes later, her oxygen saturation is 90%.

1. What risk factors does this patient have for sepsis?
2. What manifestations does she have that are consistent with sepsis and systemic inflammatory response syndrome (SIRS)?
3. What assessment should you perform immediately?
4. What would be the most likely source of infection?
5. Should you express concern about the possibility of sepsis and SIRS to the emergency department intensivist? Why or why not?

PLANNING AND IMPLEMENTATION

The priority problem for patients with septic shock is potential for multiple organ dysfunction syndrome (MODS).

Planning: Expected Outcomes

The patient with sepsis or septic shock is expected to have normal aerobic cellular metabolism. Indicators include:

- Arterial blood gases (pH, PaO₂, and PaCO₂) within the normal range
- Maintenance of a urine output of at least 20 mL/hr
- Maintenance of mean arterial blood pressure within 10 mm Hg of baseline
- Absence of multiple organ dysfunction syndrome (MODS)
- States measures to reduce the risk for sepsis

Interventions

Interventions for sepsis and septic shock focus on identifying the problem as early as possible, correcting the conditions causing it, and preventing complications. The use of a sepsis resuscitation bundle for treatment of sepsis is the standard of practice. A *bundle* is a group of two or more specific interventions that have been shown to be effective when applied together or in sequence. The sepsis resuscitation and management bundles are presented in [Table 39-6](#).

TABLE 39-6 BUNDLES FOR RESUSCITATION AND MANAGEMENT OF SEVERE SEPSIS

Sepsis Resuscitation Bundle

1. Measure serum lactate levels.
2. Obtain blood cultures *before* administering antibiotics.
3. Administer broad-spectrum antibiotic therapy within 1 hour of establishing diagnosis.
4. If either hypotension or a serum lactate level greater than 4 mmol/L (36 mg/dL) is present, institute:
 - a. IV infusion of 1000 mL of crystalloids or 300 to 500 mL of colloids over 30 minutes
 - b. If hypotension does not respond to initial fluid resuscitation by increasing the mean arterial pressure (MAP) to at least 65 mm Hg, start IV vasopressor therapy
5. If hypotension persists despite fluid resuscitation and vasopressor therapy and either septic shock is present or the serum lactate level remains greater than 4 mmol/L (36 mg/dL), use these parameters to monitor therapy effectiveness:
 - a. Central venous pressure (CVP) of at least 8 mm Hg
 - b. Central venous oxygen saturation (ScvO₂) of at least 70% or a mixed venous oxygen saturation (SvO₂) of at least 65%

Sepsis Management Bundle

1. When septic shock is present, administer low-dose steroids (200 to 300 mg hydrocortisone IV daily in divided doses) in accordance with intensive care unit (ICU) protocol.
2. Administer drotrecogin alfa (activated) for patients meeting ICU and drotrecogin criteria.
3. Administer insulin to maintain blood glucose levels at least lower than 150 mg/dL.
4. Use mechanical ventilation to maintain inspiratory plateau pressures less than 30 cm H₂O.

Adapted from Institute for Healthcare Improvement and Surviving Sepsis Campaign, 2005.

Oxygen therapy is useful whenever poor tissue perfusion and poor oxygenation are present. Oxygen is delivered in the same ways as for hypovolemic shock. However, the patient with septic shock is more likely to be mechanically ventilated. Care of the patient being mechanically ventilated is discussed in detail in [Chapter 34](#).

Drug therapy to enhance cardiac output and restore vascular volume is essentially the same as that used in hypovolemic shock (see [Chart 39-4](#)). In addition, drug therapy is needed to combat sepsis, adrenal insufficiency, hyperglycemia, and clotting problems.

Although septic shock can be caused by any organism, the most common agents are gram-negative bacteria. IV antibiotics with known activity against gram-negative bacteria are given before organisms are identified, preferably within 1 hour of a sepsis diagnosis. Multiple drugs with wide activity are prescribed, based on the site of infection and the most common geographic infections, until the actual causative organism is known. Drugs and drug categories commonly used for septic shock include vancomycin, aminoglycosides, systemic penicillin or cephalosporins, macrolides, and quinolones.

The stress of severe sepsis can cause adrenal insufficiency. Adrenal support involves providing the patient with low-dose corticosteroids during the treatment period for at least 7 days. Drugs used for this purpose are IV hydrocortisone and oral fludrocortisone (Florinef).

Patients with sepsis or septic shock usually have elevated blood glucose levels (>150 mg/dL), which is associated with a poor outcome. Insulin therapy is used to maintain blood glucose levels as close to normal as possible (80 to 110 mg/dL) or at least lower than 150 mg/dL.

During severe sepsis, patients have microvascular abnormalities and form many small clots. Heparin therapy has been used to limit clotting and to prevent the consumption of clotting factors. Additional therapy involves the use of activated protein C to manage microvascular abnormalities and prevent bleeding.

Synthetic activated protein C has been shown to stop the inflammatory responses during sepsis, preventing small clot formation and halting the progression of the disorder before septic shock occurs. Drotrecogin alfa (Xigris) is given as a continuous infusion over 4 days in patients who are considered at high risk for death. *The drug has many serious complications and, because it disrupts clotting activity, is not given to patients with other bleeding problems.* In addition, the drug is very expensive, with a single dose costing over \$7000.

Blood replacement therapy is used when hemorrhage occurs and may include clotting factors, fresh frozen plasma (FFP), whole blood, or packed red blood cells. Chapter 42 discusses in detail the care of the patient during blood replacement.

Community-Based Care

Identified sepsis should be resolved before patients are discharged from the acute care setting. Because more patients are receiving treatment on an outpatient basis and are being discharged earlier from acute care settings, more patients at home are at increased risk for sepsis.

Home Care Management

Evaluate the home environment for safety regarding infection hazards. Note the general cleanliness, especially in the kitchen and bathrooms. Chart 39-6 lists focused patient and environmental assessment data to obtain during a home visit.

CHART 39-6 HOME CARE ASSESSMENT

The Patient at Risk for Sepsis

- Assess the patient for any clinical manifestations of infection, including:
 - Temperature, pulse, respiration, and blood pressure
 - Color of skin and mucous membranes
 - The mouth and perianal area for fissures or lesions
 - Any nonintact skin area for the presence of exudates, redness, increased warmth, swelling
 - Any pain, tenderness, or other discomfort anywhere
 - Cough or any other symptoms of a cold or the flu
 - Urine; or ask patient whether urine is dark or cloudy, has an odor, or causes pain or burning during urination
- Assess patient's and caregiver's adherence to and understanding of infection prevention techniques.
- Assess home environment, including:
 - General cleanliness
 - Kitchen and bathroom facilities, including refrigeration
 - Availability and type of soap for handwashing
 - Presence of pets, especially cats, rodents, or reptiles

Teaching for Self-Management

Protecting frail patients from infection and sepsis at home is an important nursing function. Teach about the importance of self-care strategies, such as good hygiene, handwashing, balanced diet, rest and exercise, skin care, and mouth care. If patients or family members do not know how to take a temperature or read a thermometer, teach them and obtain a return demonstration. Teach patients and families to notify the health care provider immediately if fever or other signs of infection appear. General recommendations for Infection Precautions for patients at risk for sepsis are listed in Chart 39-7.

EVALUATION: OUTCOMES

Evaluate the care of the patient with sepsis or septic shock. The expected outcome is that the patient will maintain normal aerobic cellular metabolism. Specific indicators for these outcomes are listed for the priority patient problem under the Planning and Implementation section (see earlier).

CHART 39-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Infection Precautions

- Avoid crowds and other large gatherings of people, who might be ill.
- Do not share eating utensils or personal toilet articles (e.g., toothbrushes, toothpaste, washcloths, deodorant sticks) with others.
- If possible, bathe daily.
- Wash the armpits, groin, genitals, and rectal area at least twice a day with an antimicrobial soap.
- Clean your toothbrush twice weekly by either running it through the dishwasher or rinsing it in liquid laundry bleach and then rinsing out the bleach with running water.
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Wash dishes between use with hot, sudsy water, or use a dishwasher.
- Do not drink water that has been standing for longer than 15 minutes.
- Do not reuse cups and glasses without washing them.
- Do not change pet litter boxes.
- Take your temperature at least once a day.
- Refrigerate and prepare food appropriately. Do not eat raw or undercooked meat, fish, poultry, or eggs.
- Report any of the following signs or symptoms of infection to your physician immediately:
 - Temperature greater than 100° F (38° C)
 - Persistent cough (with or without sputum)
 - Pus or foul-smelling drainage from any open skin area or normal body opening
 - Presence of a boil or abscess
 - Urine that is cloudy or foul-smelling or causes burning on urination
- Do not dig in the garden or work with houseplants.
- Use antibacterial cleansers to clean kitchen and bathroom surfaces at least twice each week. If you clean these areas yourself, wear rubber or vinyl work gloves while cleaning.
- Use a condom when having sex.
- Take all drugs as prescribed.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of hypovolemic shock?

- Pulse rapid and thready
- Pulse pressure narrowed
- Respirations rapid and shallow
- Oxygen saturation by pulse oximetry decreased
- Skin cyanosis or pallor (in lighter-skinned patients)
- Skin cool and clammy
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Patient is restless or anxious
- Patient has a urine output that is less than expected compared with fluid intake
- Patient states he or she is thirsty

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of hypovolemic shock?

Perform and interpret physical assessment, including:

- Taking vital signs
- Auscultating all lung fields
- Monitoring oxygen saturation by pulse oximetry
- Assessing cognition (Mini-Mental State Examination [MMSE])
- Checking incisions, body orifices, and under the patient for signs of active bleeding
- Assessing the skin for bruises and petechiae

- Examining all body areas for swelling or discoloration that could indicate internal bleeding

Interpret laboratory values:

- Arterial blood gas values: pH lower than 7.35
- Elevated serum lactate levels
- Hemorrhage
 - Decreased hematocrit and hemoglobin
 - Decreased total red blood cells and platelets
- Dehydration
 - Elevated red blood cell count, hematocrit, and hemoglobin
 - Elevated white blood cell count

Respond by:

- Applying oxygen
- Assisting the patient to shock position (head and chest flat or elevated to no more than 30 degrees; legs elevated)
- Notifying the Rapid Response Team
- Ensuring placement of venous access
- Increasing IV fluid infusion rate

On what should you REFLECT?

- Observe patient for evidence of improved circulation and oxygenation (see [Chapter 35](#)).
- Think about what may have caused the hypovolemia.
- Think about how the nurse may have identified the problem sooner.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category

Safe and Effective Care Environment

- Use strict aseptic techniques when performing invasive procedures, changing dressings, and handling nonintact skin.
- Use good handwashing techniques before providing any care to a patient who is either immunocompromised or immune deficient.

Health Promotion and Maintenance

- Identify patients at high risk for infection due to age, disease, or the environment.
- Teach the patient and family about the clinical manifestations of infection and when to seek medical advice.

Psychosocial Integrity

- Assess all patients at risk for shock for a change in affect, reduced cognition, altered level of consciousness, and increased anxiety.

- Stay with the patient in shock.
- Reassure patients who are in shock that the appropriate interventions are being instituted.

Physiological Integrity

- Assess the immunocompromised patient every shift for infection.
- Assess the skin integrity of the patient with reduced immune function at least every shift.
- Immediately assess vital signs of patients who have a change in level of consciousness, increased thirst, or anxiety.
- Assess for changes in pulse rate and quality rather than blood pressure as an indicator of shock.
- Give oxygen to any patient in shock.
- Assess hourly urine output to evaluate the adequacy of treatment for hypovolemic shock.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Plan continuity of care between health care agencies or hospital and home when discharging patients who have had cardiac interventions or surgeries.
2. Explain the role of the interdisciplinary team in cardiac rehabilitation.

Health Promotion and Maintenance

3. Differentiate between modifiable and nonmodifiable risk factors for coronary artery disease (CAD).
4. Develop a teaching plan for patients at risk for CAD regarding cardiovascular risk modification programs and lifestyle changes.

Psychosocial Integrity

5. Assess patient and family responses to acute coronary events, especially myocardial infarction (MI).

Physiological Integrity

6. Compare and contrast the clinical manifestations of stable angina, unstable angina, and MI.

7. Interpret physical and diagnostic assessment findings in patients who have CAD.
8. Prioritize nursing care for patients who have chest pain.
9. Teach patients and families about drug therapy for CAD.
10. Explain the nursing care for patients who have thrombolysis for an MI.
11. Develop a plan of care for the patient who has a percutaneous transluminal coronary angioplasty.
12. Delineate postoperative care for the patient who has coronary artery bypass graft (CABG) surgery, including monitoring for complications.
13. Identify the special needs of older adults having coronary artery bypass graft (CABG) surgery.
14. Differentiate care for patients having traditional CABG surgery, minimally invasive direct coronary artery bypass, off-pump CABG, and transmyocardial laser revascularization.

Coronary artery disease (CAD), also called *coronary heart disease (CHD)* or simply *heart disease*, is the single largest killer of American men and women in all ethnic groups. When the arteries that supply the **myocardium** (heart muscle) are diseased, the heart cannot pump blood effectively to adequately perfuse vital organs and peripheral tissues. The organs and tissues need oxygen in arterial blood for survival.

When *oxygenation* and *perfusion* are impaired, the patient can have life-threatening clinical manifestations and possibly death.

The incidence of CAD has declined over the past decade. This decline is due to many factors, including increasingly effective treatment and an increased awareness and emphasis on reducing major cardiovascular risk factors (e.g.,

hypertension, smoking, high cholesterol). Some coronary events occur in patients without traditional risk factors.

Pathophysiology

Coronary artery disease (CAD) is a broad term that includes chronic stable angina and acute coronary syndromes. It affects the arteries that provide blood, oxygen, and nutrients to the myocardium. When blood flow through the coronary arteries is partially or completely blocked, ischemia and infarction of the myocardium may result. Ischemia occurs when *insufficient oxygen* is supplied to meet the requirements of the myocardium. **Infarction** (necrosis, or cell death) occurs when severe ischemia is prolonged and *decreased perfusion* causes irreversible damage to tissue.

Chronic Stable Angina Pectoris

Angina pectoris is chest pain caused by a temporary imbalance between the coronary arteries' ability to supply oxygen and the cardiac muscle's demand for *oxygen*. **Ischemia** (lack of oxygen) that occurs with angina is limited in duration and does not cause permanent damage of myocardial tissue.

Angina may be of two main types: stable angina and unstable angina. **Chronic stable angina (CSA)** is chest discomfort that occurs with moderate to prolonged exertion in a pattern that is familiar to the patient. The frequency, duration, and intensity of symptoms remain the same over several months. CSA results in only slight limitation of activity and is usually associated with a *fixed* atherosclerotic plaque. It is usually relieved by nitroglycerin or rest and often is managed with drug therapy. Rarely does CSA require aggressive treatment. Unstable angina is discussed in the following Acute Coronary Syndromes section.

Acute Coronary Syndromes

The term **acute coronary syndrome (ACS)** is used to describe patients who have either *unstable angina* or an acute myocardial infarction. In ACS, it is believed that the atherosclerotic plaque in the coronary artery *ruptures*, resulting in platelet aggregation ("clumping"), thrombus (clot) formation, and vasoconstriction (Fig. 40-1). The amount of disruption of the atherosclerotic plaque determines the degree of coronary artery obstruction (blockage) and the specific disease process. The artery has to have at least 40% plaque accumulation before it starts to block blood flow.

Historically, an acute myocardial infarction (MI) was diagnosed by the presence of ST-segment elevation on the 12-lead electrocardiogram (ECG) (see discussion of the normal ECG in Chapter 36). However, all patients do not present with this finding. Instead, they are classified into one of three categories according to the presence or absence of ST-segment elevation on the ECG and positive troponin markers (see Chapter 35 for discussion of troponins):

- ST-elevation MI (STEMI) (traditional manifestation)
- Non-ST-elevation MI (NSTEMI) (common in women)
- Unstable angina

Unstable Angina Pectoris. *Unstable angina* (the most commonly used term) is chest pain or discomfort that occurs at rest or with exertion and causes severe activity limitation. An increase in the number of attacks and in the intensity of the pressure indicates unstable angina. The pressure may last longer than 15 minutes or may be poorly relieved by rest or nitroglycerin. Unstable angina describes a variety of

disorders, including *new-onset angina*, *variant (Prinzmetal's) angina*, and *pre-infarction angina*. Patients with *unstable angina* will present with ST changes on a 12-lead ECG but will not have changes in troponin or creatine kinase (CK) levels.

New-onset angina describes the patient who has his or her first angina symptoms, usually after exertion or other increased demands on the heart. **Variant (Prinzmetal's) angina** is chest pain or discomfort resulting from coronary artery spasm and typically occurs after rest. **Pre-infarction angina** refers to chest pain that occurs in the days or weeks before an MI.

Myocardial Infarction. The most serious acute coronary syndrome is myocardial infarction (MI), often referred to as *acute MI* or *AMI*. Undiagnosed or untreated angina can lead to this very serious health problem. AMI is further divided by the American College of Cardiology (ACC)/AHA into non-ST-elevation MI (NSTEMI) and ST-elevation MI (STEMI) (Anderson, 2007). Patients presenting with NSTEMI typically have ST and T-wave changes on 12-lead ECG. This indicates myocardial ischemia. Cardiac enzymes may be initially normal but elevate over the next 6 to 12 hours. Patients presenting with STEMI typically have ST elevation in two contiguous leads on a 12-lead ECG. This indicates myocardial infarction/necrosis and requires immediate treatment.

Myocardial infarction (MI) occurs when myocardial tissue is abruptly and severely deprived of oxygen. When blood flow is quickly reduced by 80% to 90%, ischemia develops. Ischemia can lead to injury and necrosis of myocardial tissue if blood flow is not restored. Most MIs are the result of atherosclerosis of a coronary artery, rupture of the plaque, subsequent thrombosis, and **occlusion** (blockage) of blood flow. Other factors may be involved, however, such as coronary artery spasm, platelet aggregation, and emboli from mural thrombi (thrombi lining the walls of the cardiac chambers).

Often MIs begin with infarction of the subendocardial layer of cardiac muscle. This layer has the longest myofibrils in the heart, the greatest oxygen *demand*, and the poorest oxygen *supply*. Around the initial area of infarction (zone of necrosis) in the subendocardium are two other zones: (1) the zone of injury—tissue that is injured but not necrotic; and (2) the zone of ischemia—tissue that is oxygen deprived. This pattern is illustrated in Fig. 40-2.

WOMEN'S HEALTH CONSIDERATIONS

Many women with symptomatic ischemic heart disease or abnormal stress testing do not have normal coronary angiography (Shaw et al., 2009). Studies implicate microvascular disease or endothelial dysfunction or both as the causes for risk for CAD in women. Endothelial dysfunction is defined as the "inability of the arteries and arterioles to dilate due to inability of the endothelium to produce nitric oxide, a relaxant of vascular smooth muscle" (Bellasi et al., 2007).

Women typically have smaller coronary arteries and frequently have plaque that breaks off and travels into the small vessels to form an embolus (clot). "Positive remodeling" or outward remodeling (lesions that protrude outward) is more common in women (Bellasi et al., 2007). This outpouching may be missed on coronary angiography.

Infarction is a dynamic process that does not occur instantly. Rather, it evolves over a period of several hours. **Hypoxia** (decreased oxygen) from ischemia may lead to local vasodilation of blood vessels and acidosis. Potassium, calcium, and

FIG. 40-1 A cross section of an atherosclerotic coronary artery.

magnesium imbalances, as well as acidosis at the cellular level, may lead to changes in normal conduction and contractile functions. Catecholamines (epinephrine and norepinephrine) released in response to hypoxia and pain may increase the heart's rate, contractility, and afterload. These factors increase *oxygen* requirements in tissue that is already oxygen deprived. This may lead to life-threatening ventricular dysrhythmias. The area of infarction may extend into the zones of injury and ischemia. The actual extent of the zone of infarction depends on three factors: collateral circulation, anaerobic metabolism, and workload demands on the myocardium.

The infarction may involve only the subendocardium (called a **subendocardial MI**) or may spread to the epicardium or to all three layers of cardiac muscle. When all three

layers are involved, the MI is termed **transmural**. Subendocardial MIs have less effect on wall motion and cardiac output than do transmural infarctions. When fewer grams of myocardium are affected, the characteristic "Q" wave on the ECG, which may also indicate an old infarction, may not appear.

Obvious physical changes do not occur in the heart until 6 hours after the infarction, when the infarcted region appears blue and swollen. *These changes explain the need for intervention within the first 4 to 6 hours of symptom onset!* After 48 hours, the infarcted area turns gray with yellow streaks as neutrophils invade the tissue and begin to remove the necrotic cells. By 8 to 10 days after infarction, granulation tissue forms at the edges of the necrotic tissue. Over a 2- to 3-month period, the necrotic area eventually develops into a shrunk, thin, firm scar. Scar tissue permanently changes the size and

FIG. 40-2 Electrocardiographic changes and patterns associated with myocardial infarction.

shape of the entire left ventricle, called **ventricular remodeling**. Remodeling may decrease left ventricular function, cause heart failure, and increase morbidity and mortality. The scarred tissue does not contract nor does it conduct electrically. Thus this area is often the cause of chronic ventricular dysrhythmias surrounding the infarcted zone.

The patient's response to an MI also depends on which coronary artery or arteries were obstructed and which part of the left ventricle wall was damaged: anterior, septal, lateral, inferior, or posterior. Fig. 35-3 in Chapter 35 shows the location of the major coronary arteries.

Obstruction of the left anterior descending (LAD) artery causes *anterior* or *septal* MIs because it perfuses the anterior wall and most of the septum of the left ventricle. Patients with anterior wall MIs (AWMIs) have the highest mortality rate because they are most likely to have left ventricular failure and dysrhythmias from damage to the left ventricle.

The circumflex artery supplies the lateral wall of the left ventricle and possibly portions of the posterior wall or the sinoatrial (SA) and atrioventricular (AV) nodes. Patients with obstruction of the circumflex artery may experience a *posterior* wall MI (PWMI) or a *lateral* wall MI (LWMI) and sinus dysrhythmias.

In most people, the right coronary artery (RCA) supplies most of the SA and AV nodes, as well as the right ventricle and inferior or diaphragmatic portion of the left ventricle. Patients with obstruction of the RCA often have **inferior wall MIs**. About half of all inferior wall MIs are associated with an occlusion of the RCA causing significant damage to the right ventricle. *Thus it is important to obtain a "right-sided" ECG to assess for right ventricular involvement.*

Etiology and Genetic Risk

Atherosclerosis is the primary factor in the development of CAD. Numerous risk factors contribute to atherosclerosis and subsequently to CAD (also see Chapter 38).

Nonmodifiable risk factors are personal characteristics that cannot be altered or controlled. These risk factors, which interact with each other, include age, gender, family history, and ethnic background. People with a family history of CAD are at high risk for developing the disease. These factors are discussed in more detail in Chapter 35.

WOMEN'S HEALTH CONSIDERATIONS

Age is the most important risk factor for developing CAD in women. The older a woman is, the more likely she will have the disease. When compared with men, women are usually 10 years older when they have CAD. In addition, women who have MIs have a greater risk for dying during hospitalization. When they are older than 40 years, women are more likely than men to die within 1 year after their MI (AHA, 2010).

Modifiable risk factors are lifestyle choices that can be controlled by the patient, such as smoking and obesity. These factors are described later in the Health Promotion and Maintenance section of this chapter.

Incidence/Prevalence

According to the American Heart Association (AHA) (2010), 64% of women and 50% of men who had a myocardial infarction (MI) ("heart attack") were not aware that they had CAD. The average age of a person having a first MI is 64.5 years for men and 70.3 years for women (AHA, 2010). Almost 30% of patients who have an MI die within 5 years after the event (AHA, 2010).

Every 25 seconds, a person in the United States has a major coronary event and 452,000 people die each year from an MI. Many people die from coronary heart disease without being hospitalized. Most of these are sudden deaths caused by cardiac arrest (AHA, 2010).

WOMEN'S HEALTH CONSIDERATIONS

Premenopausal women have a lower incidence of MI than men. However, for postmenopausal women in their 70s or older, the incidence of MI equals that of men. Family history is also a risk factor for women; those whose parents had CAD are more susceptible to the disease. Women with abdominal obesity (android shape) and metabolic syndrome (described on p. 834) are also at increased risk for CAD (Bellasi et al., 2007).

Many patients who survive MIs are not able to return to work. CAD is the leading cause of premature, permanent disability in the United States, accounting for about 20% of disability allowances by the Social Security Administration.

Health Promotion and Maintenance

Ninety-five percent of sudden cardiac arrest victims die before reaching the hospital, largely because of ventricular fibrillation ("v fib"). To help combat this problem, automatic external defibrillators (AEDs) are found in many public places, such as in shopping centers and on airplanes. Employees are taught how to use these devices if a sudden cardiac

arrest occurs. Some patients with diagnosed CAD have AEDs in their homes or at work. How to use this device is described on p. 738 in Chapter 36.

Health promotion efforts are directed toward controlling or altering modifiable risk factors for CAD. Some of these factors have a genetic basis, which is described elsewhere in this text. Common risk factors include:

- Elevated serum lipid levels
- Tobacco use
- Limited physical activity
- Hypertension
- Diabetes mellitus
- Obesity
- Excessive alcohol
- Stress

! NURSING SAFETY PRIORITY

Action Alert

For patients at risk for coronary artery disease (CAD), especially MI, assess specific risk factors and implement an individualized health teaching plan. Teach people who have one or more of these risk factors the importance of modifying or eliminating them to decrease their chances of CAD (Chart 40-1).

CULTURAL AWARENESS

Several groups have a higher genetic risk for CAD than others. African-American and Hispanic women have higher CAD risk factors than white women of the same socioeconomic status. Of American Indians and Alaskan Natives 18 years of age and older, about 64% of men and 81% of women have one or more CAD risk factors (hypertension [HTN], smoking, high cholesterol, excess weight, or diabetes mellitus). The leading cause of death for both men and women in the Euro-American population is cardiac disease, even though they may not have genetic predispositions to developing cardiovascular risk factors (AHA, 2010).

Reducing Elevated Serum Lipid Levels

The risk for CAD rises as serum cholesterol and triglyceride levels increase. In addition to measuring the total serum cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglyceride (TG) levels are important in assessing risk for CAD. LDL cholesterol is the “bad” type, and HDL cholesterol is referred to as “good” because it has protective properties. *Elevated levels of LDL combined with low levels of HDL increase the risk for MI.* Total serum cholesterol levels also put the patient at a higher risk for developing an MI. According to the AHA (2010), a 10% reduction in serum cholesterol may result in a 30% reduction in the incidence of CAD and MI. The *fasting* total cholesterol should be below 130 mg/dL. The AHA (2010) defines levels of fasting total cholesterol as:

- 130-159 mg/dL—borderline high
- 160-189 mg/dL—high
- ≥190 mg/dL—very high

The desired LDL level in patients who are at high risk or have existing CAD is less than 70 mg/dL. For patients at low or moderate risk, LDL should also be substantially less than 100 mg/dL (AHA, 2010). HDL cholesterol levels should be above 40 mg/dL, although this recommendation may soon be changed to a higher level. The recommended triglyceride level is less than 135 mg/dL in women and 150 mg/dL in men (Pagana & Pagana, 2010).

Approaches to decrease lipids are focused on diet, exercise, and drug therapy that lowers cholesterol and triglyceride levels. Teach patients with elevated lipid levels to:

- Reduce intake of saturated fats to less than 7% of total calories
- Avoid *trans* fatty acids
- Consume less than 200 mg per day of cholesterol
- Participate in daily physical activity
- Manage weight

CHART 40-1 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Coronary Artery Disease

Smoking

- If you smoke, quit.
- If you don't smoke, don't start.

Diet

- Consume sufficient calories for your body to include:
 - Less than 7% from saturated fats
 - Avoiding *trans* fatty acids
- Limit your cholesterol intake to less than 200 mg/day.
- Limit your sodium intake as specified by your health care provider.

Cholesterol

- Have your lipid levels checked regularly.
- If your cholesterol and LDL levels are elevated, follow your health care provider's advice.

Physical Activity

- If you are middle-aged or older or have a history of medical problems, check with your health care provider before starting an exercise program.
- Appropriate exercise should be enjoyable, burn 400 calories per session, and sustain a heart rate of 120 to 150 beats/min, depending on your age.

- Exercise periods should be at least 20 to 30 minutes long with 10-minute warm-up and 5-minute cool-down periods.
- If you cannot exercise moderately three to five times each week, walk daily for 30 minutes at a comfortable pace.
- If you cannot walk 30 minutes daily, walk any distance you can (e.g., park farther away from a site than necessary; use the stairs, not the elevator, to go one floor up or two floors down).

Diabetes

- Manage your diabetes with your health care provider.

Blood Pressure

- Have your blood pressure checked regularly.
- If your blood pressure is elevated, follow your health care provider's advice.
- Continue to monitor your blood pressure at regular intervals.

Obesity

- Avoid severely restrictive or fad diets.
- Restrict intake of saturated fats, simple sugars, and cholesterol-rich foods.
- Increase your physical activity.

Using Complementary and Alternative Therapies

Teach patients that adding omega-3 fatty acids from fish and plant sources has been effective for some patients in reducing lipid levels, stabilizing atherosclerotic plaques, and reducing sudden death from an MI. The preferred source of omega-3 acids is from fish three times a week or a daily fish oil nutritional supplement (1-2 g/day) containing eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (AHA, 2010). Plant sources (flaxseed, flaxseed oil, walnuts, and canola oil) contain α -linolenic acid, and the conversion of α -linolenic acid to EPA and DHA is not as efficient in patients who consume a typical Western diet (Surette, 2008). Lovaza (omega-3 fatty acids) is a new medication approved by the Federal Drug Administration (FDA) and is used to reduce very high triglycerides (>500 mg/dL) levels. Lovaza has not been proven to prevent heart attacks or stroke.

Garlic supplements may also have a small effect on reducing lipid levels, but they have not been shown to prevent MI. Patients often take a number of other supplements, such as vitamin E, coenzyme Q10, Pantestin, and vitamin B complex to decrease the risk for heart disease. None of these substances has been found to be helpful in reducing coronary artery disease.

Eliminating Tobacco Use

In the United States, an estimated 23% of men and 18% of women smoke cigarettes, putting them at increased risk for MI (AHA, 2010). About five million U.S. men and women chew tobacco, with the highest rates in the South and rural areas. Tobacco use and **passive smoking** from “second-hand smoke” (also called *environmental smoke*) substantially reduce blood flow in the coronary arteries.

Tobacco use, especially cigarette smoking, accounts for over one third of deaths from CAD. It enhances the process of atherosclerosis through mechanisms that are still poorly understood. Nicotine begins the release of catecholamines, resulting in an increased heart rate and peripheral vasoconstriction. This action causes increases in blood pressure (BP), cardiac afterload, and oxygen consumption. Cigarette smoking has also been found to cause endothelial dysfunction and increased vessel wall thickness. This process increases the risk for clot formation and vessel occlusion. The resulting hypertension may exacerbate the atherosclerotic process by increasing vessel wall permeability. Another problem with cigarette smoking is the production of carbon monoxide, which has been found to decrease the oxygen content in arterial blood. The good news is that when cigarette smoking is stopped, the risk for CAD decreases. A person who stops smoking may decrease the risk for CAD by as much as 80% in 1 year. Reducing the tar and nicotine content of the cigarettes smoked does not reduce the risk for CAD (AHA, 2010).

Ask about tobacco use, and advise the tobacco user and family members who smoke to quit using this harmful substance. Teach all patients to avoid environmental tobacco smoke at work and at home if at all possible. Additional information about tobacco use and smoking cessation is found in [Chapters 32 and 35](#).

Increasing Physical Activity

Physical inactivity may be the most important risk factor for the general population. Less-active, less-fit people have a 30% to 50% greater risk for developing high blood pressure (BP), which predisposes to CAD. Physical inactivity is more

common among women than men, among African Americans and Hispanics than Euro-Americans, among older adults than younger adults, and among the less affluent than the more affluent (AHA, 2010). The causes for these differences are not known. Teach patients that regular physical activity helps maintain body weight and muscle mass while improving BP and lipid values.

Moderate-intensity activities like walking are associated with a major reduction in CAD risk. However, intense exercising may contribute to plaque rupture and increase the number of cardiac episodes. Teach people that participating in exercise for 30 minutes a day can reduce hypertension and increase secretions of endorphins. It also leads to decreased smoking and eating, improved metabolism, and a stronger feeling of well-being. Other benefits include decreased blood clotting and higher plasma HDL levels, increased heart volume, increased cardiac capillary blood flow, and decreased heart rate. Physical activity does not increase collateral circulation or reduce the size of existing plaques.

Managing Other Factors

One in three Americans has *hypertension* (HTN). This disease increases the workload of the heart, which increases the risk for MI. The cause of primary HTN is not known. However, it is easily detected and usually controllable. About half of patients having a first MI have a BP greater than 160/95 mm Hg. Ways to manage hypertension and therefore reduce the risk for CAD are described in [Chapter 38](#).

Diabetes mellitus (DM) is a major risk factor for heart disease. A woman with diabetes mellitus is twice as likely to develop CAD than a woman without DM. Heart disease is the leading cause of diabetic-related death in both men and women. Most adults with diabetes also have hypertension. [Chapter 67](#) discusses vascular complications of diabetes in detail.

Obesity is strongly associated with the development of hypertension, diabetes, and increased serum lipid levels. Women with fat deposited around their waists are at the highest risk for CAD. Teach the importance of weight management to help prevent these chronic and potentially life-threatening diseases.

Alcohol may help prevent or contribute to the development of CAD, depending on the amount consumed. Excessive consumption, described as having more than 3 ounces (90 mL) per day, can lead to increased heart disease, hypertension, and metabolic syndrome, described in the next section. A lower amount may help prevent CAD (Suzuki et al., 2009).

CULTURAL AWARENESS

Modifiable risk factors vary for people of different racial and ethnic backgrounds. Some of the differences may be explained by lack of access to health care for some groups or by genetic factors. American Indians, for example, have the highest percentage of smokers among women and men. However, many of these people have poor access to care or have language barriers in a predominantly English-speaking, Euro-American health care system. Nutritional preferences may also explain some of the differences. For instance, according to the AHA (2010), high cholesterol is more common in African-American and Hispanic populations. Diets higher in fat and cholesterol are often less expensive and may be a factor in explaining differences, and obesity is more common in these groups. Genetic factors may also contribute to the differences among ethnic groups.

TABLE 40-1 INDICATORS OF RISK FACTORS FOR METABOLIC SYNDROME

RISK FACTOR	INDICATOR
Hypertension	Either blood pressure of 130/85 mm Hg or higher or taking antihypertensive drug(s)
Decreased HDL-C (usually with high LDL-C) level	Either HDL-C <40 mg/dL for men or <50 mg/dL for women or taking an anticholesterol drug
Increased level of triglycerides	Either 150 mg/dL or higher or taking an anticholesterol drug
Increased fasting blood glucose (due to diabetes, glucose intolerance, or insulin resistance)	Either 100 mg/dL or higher or taking antidiabetic drug(s)
Large waist size (excessive abdominal fat causing central obesity)	40 inches (102 cm) or greater for men or 35 inches (89 cm) or greater for women

HDL-C, High-density lipoprotein-cholesterol; LDL-C, low-density lipoprotein-cholesterol.

A person's response to *emotional stress* may also be associated with heart disease. Work stress, in particular, may be associated with left ventricular hypertrophy. During times of stress, increased heart rate increases the work of the heart, thus causing changes in the left ventricle.

Metabolic syndrome, also called *syndrome X*, has been recognized as a risk factor for cardiovascular (CV) disease and is being aggressively researched. Patients who have three of the factors in Table 40-1 are diagnosed with **metabolic syndrome**. This health problem increases the risk for developing diabetes and CAD. About 47 million people in the United States have metabolic syndrome (AHA, 2010). This increase is likely due to physical inactivity and the current obesity epidemic. Management is aimed at reducing risks, managing hypertension, and preventing complications.

Elevated levels of serum *homocysteine*, an amino acid, have been associated with an increased incidence of CAD. However, research findings are not consistent regarding its risk. Vitamin B supplements have been thought to decrease homocysteine. Recent studies suggest that vitamin B is not effective as secondary prevention, but few studies have been conducted on vitamin B as a primary preventive measure (Ebbing et al., 2008).

Patients with multiple modifiable risk factors have several times the risk for CAD as those without these characteristics. Although many factors place a person at risk for heart disease, there are well-documented, effective ways of promoting cardiovascular health. *The most important interdisciplinary intervention is health teaching.*

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

An older client has a history of stable angina. Which modifiable risk factors will the nurse assess to guide the client's teaching plan?

Select all that apply.

- A. Older age
- B. Tobacco use
- C. Activity level
- D. Serum lipid levels
- E. Family history
- F. Weight

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

If symptoms of CAD are present at the time of the interview, delay collecting data until interventions for symptom relief, vital sign instability, and dysrhythmias are started and discomfort resolves. If the patient had pain, ask about how he or she has managed the discomfort and other symptoms and which drugs he or she may be taking. When the patient is pain-free, obtain information about family history and modifiable risk factors, including eating habits, lifestyle, and physical activity levels. Ask about a history of smoking and how much alcohol is consumed each day. Collaborate with the dietitian to assess current body mass index (BMI) and weight.

Physical Assessment/Clinical Manifestations

Rapid assessment of the patient with chest pain or other presenting symptoms is crucial. It is important to differentiate among the types of chest pain and to identify the source. Question the patient to determine the characteristics of the discomfort. Patients may deny pain, however, and report that they feel "pressure." Appropriate questions to ask concerning the discomfort include onset, location, radiation, intensity, duration, and precipitating and relieving factors.

CULTURAL AWARENESS

African Americans and women tend to delay seeking treatment for MI and therefore have higher mortality rates than Euro-Americans. One contributing factor to this delay is a greater incidence of dyspnea as an acute symptom among these groups rather than the classic pain more typical of other groups (AHA, 2010).

If pain is present, ask the patient if the pain is in the chest, epigastric area, jaw, back, shoulder, or arm. Ask him or her to rate the pain on a scale of 0 to 10, with 10 being the highest level of discomfort. Some patients describe the discomfort as tightness, a burning sensation, pressure, or indigestion.

WOMEN'S HEALTH CONSIDERATIONS

Many women of any age experience atypical angina. **Atypical angina** manifests as indigestion, pain between the shoulders, an aching jaw, or a choking sensation that occurs with exertion. These symptoms typically manifest during stressful circumstances or during activities of daily living. Women may curtail activity as a result of angina, and health care providers need to ask about changes in routine. Symptoms in women typically include fatigue, sleep disturbance, and dyspnea.

Chart 40-2 compares and contrasts angina and infarction pain. Because angina pain is ischemic pain, it usually improves when the imbalance between oxygen supply and demand is resolved. For example, rest reduces tissue demands and nitroglycerin improves oxygen supply. Discomfort from a myocardial infarction (MI) does not usually resolve with these measures. *Also ask about any associated symptoms, including*

CHART 40-2 KEY FEATURES

Angina and Myocardial Infarction

ANGINA	MYOCARDIAL INFARCTION
- Substernal chest discomfort: - Radiating to the left arm - Precipitated by exertion or stress (or rest in variant angina) - Relieved by nitroglycerin or rest - Lasting less than 15 min - Few, if any, associated symptoms	- Pain or discomfort: - Substernal chest pain/pressure radiating to the left arm - Pain or discomfort in jaw, back, shoulder, or abdomen - Occurring without cause, usually in the morning - Relieved only by opioids - Lasting 30 min or more - Frequent associated symptoms: - Nausea/vomiting - Diaphoresis - Dyspnea - Feelings of fear and anxiety - Dysrhythmias - Fatigue - Palpitations - Epigastric distress - Anxiety - Dizziness - Disorientation/acute confusion - Feeling “short of breath”

CONSIDERATIONS FOR OLDER ADULTS

The presence of associated symptoms without chest discomfort is significant. In up to 40% of all patients with MI, primarily older women and patients with diabetes, chest pain or discomfort may be mild or absent. Instead, they have associated symptoms. *Some older patients may think they are having indigestion and therefore not recognize that they are having an MI. Others report shortness of breath as the only symptom.* The major manifestation of MI in people older than 80 years may be disorientation or acute confusion because of poor cardiac output.

In some older adults with MI, absence of chest pain may be due to cognitive impairment or inability to verbalize pain sensation. However, in most cases it is probably the result of increased collateral circulation. Silent myocardial ischemia increases the incidence of new coronary events and should be treated aggressively.

nausea, vomiting, diaphoresis, dizziness, weakness, palpitations, and shortness of breath.

Assess **blood pressure** and **heart rate**. Interpret the patient's cardiac rhythm and presence of **dysrhythmias**. Sinus tachycardia with premature ventricular contractions (PVCs) frequently occurs in the first few hours after an MI.

Next assess **distal peripheral pulses** and **skin temperature**. The skin should be warm with all pulses palpable. In the patient with unstable angina or MI, poor cardiac output may be manifested by cool, diaphoretic (“sweaty”) skin and diminished or absent pulses. *Auscultate for an S₃ gallop, which often indicates heart failure—a serious and common complication of MI.* Assess the **respiratory rate** and breath sounds for signs of heart failure. An increased respiratory rate is common because of anxiety and pain, but *crackles or wheezes* may indicate **left-sided heart failure**. An S₄ heart sound is a common finding in the patient who has had a previous MI or hypertension. Assess for the presence of **jugular venous distention** and **peripheral edema**.

The patient with MI may experience a *temperature elevation* for several days after infarction. Temperatures as high as 102° F (38.9° C) may occur in response to myocardial necrosis, indicating the inflammatory response.

Psychosocial Assessment

Denial is a common early reaction to chest discomfort associated with angina or MI. On average, the patient with an acute MI waits more than 2 hours before seeking medical attention. Often he or she rationalizes that symptoms are due to indigestion or overexertion. In some situations, denial is a normal part of adapting to a stressful event. However, denial that interferes with identifying a symptom such as chest discomfort can be harmful. Explain the importance of reporting any discomfort to the health care provider.

Fear, depression, anxiety, and anger are other common reactions of many patients and their families. Assist in identifying these feelings. Encourage them to explain their understanding of the event, and clarify any misconceptions.

Laboratory Assessment

Although there is no single ideal test to diagnose MI, the most common laboratory tests include troponins T and I, creatine kinase-MB (CK-MB), and myoglobin. These cardiac markers are specific for MI and cardiac necrosis. Troponins T and I and myoglobin rise quickly. CK-MB is the most specific marker for MI but does not peak until about 24 hours after the onset of pain. These tests are described in more detail in [Chapter 35](#).

Imaging Assessment

Unless there is associated cardiac dysfunction (e.g., valve disease) or heart failure, a chest x-ray is not diagnostic for angina or MI.

Thallium scans use radioisotope imaging to assess for ischemia or necrotic muscle tissue related to angina or myocardial infarction (MI). Areas of decreased or absent perfusion, referred to as *cold spots*, identify ischemia or infarction. Thallium may be used with the exercise tolerance test. Dipyrindamole (Persantine) thallium scanning (DTS) may also be used.

Contrast-enhanced cardiovascular magnetic resonance (CMR) may also be done as a noninvasive approach to detect MI. **Echocardiography** may be used to visualize the structures of the heart.

Use of the 64-slice **computed tomography coronary angiography (CTCA)** has been found to be helpful in diagnosing coronary artery disease in symptomatic patients identified as having a “low- or intermediate-pretest probability” risk for CAD. This new generation of high-speed computed tomography (CT) scanners is becoming a highly reliable, noninvasive way to evaluate CAD (Weustink et al., 2010).

Other Diagnostic Assessment

Twelve-lead electrocardiograms (ECGs) allow the health care provider to examine the heart from varying perspectives. By identifying the lead(s) in which ECG changes are occurring, the health care provider can identify both the occurrence and the location of ischemia (angina) or necrosis (infarction). In addition to the traditional 12-lead ECG, the health care provider may request a “right-sided” or 18-lead ECG to determine whether ischemia or infarction has occurred in the right ventricle.

An ischemic myocardium does not repolarize normally. Thus 12-lead ECGs obtained during an angina episode reveal ST depression, T-wave inversion, or both. **Variant angina**, caused by coronary vasospasm (vessel spasm), usually causes elevation of the ST segment during angina attacks. These ST and T-wave changes usually subside when the ischemia is resolved and pain is relieved. However, the T wave may remain flat or inverted for a period of time. If the patient is not experiencing angina at the moment of the test, the ECG is usually normal unless he or she has evidence of an old MI.

When infarction occurs, one of three ECG changes is usually observed: ST-elevation MI (STEMI), T-wave inversion, or non-ST-elevation MI (NSTEMI). An abnormal Q wave (wider than 0.04 seconds or more than one-third the height of the QRS complex) may develop, depending on the amount of myocardium that has necrosed. Women having an MI often present with an NSTEMI or T-wave inversion.

The Q wave may develop because necrotic cells do not conduct electrical stimuli. Hours to days after the MI, the ST-segment and T-wave changes return to normal. However, when the Q wave exists, it may become permanent. The Q waves may disappear after a number of years, but their absence does not necessarily mean that the patient has not had an MI.

After the acute stages of an angina episode or MI, the health care provider often requests an *exercise tolerance test* (stress test) on a treadmill to assess for ECG changes consistent with ischemia, evaluate medical therapy, and identify those who might benefit from invasive therapy. Pharmacologic stress-testing agents such as dobutamine (Dobutrex) may be used instead of the treadmill. Treadmill exercise testing is only moderately accurate for women when compared with men (Bellasi et al., 2007). In women with suspected CAD, stress echocardiography or single photon emission computed tomography (SPECT) should be performed.

Cardiac catheterization may be performed to determine the extent and exact location of coronary artery obstructions. It allows the cardiologist and cardiac surgeon to identify patients who might benefit from percutaneous transluminal coronary angioplasty (PTCA) and stent placement or from coronary artery bypass grafting (CABG). Each of the diagnostic tests in this section is described in detail in [Chapter 35](#).

ANALYSIS

The patient with coronary artery disease (CAD) may have either angina or MI. If MI is suspected or cannot be completely ruled out, the patient is admitted to a telemetry unit for continuous monitoring or to a critical care unit if hemodynamically unstable.

The priority problems for most patients with CAD are:

1. Acute Pain related to imbalance between myocardial oxygen supply and demand
2. Inadequate tissue perfusion (cardiopulmonary) related to interruption of arterial blood flow
3. Activity Intolerance related to fatigue caused by imbalance between oxygen supply and demand
4. Ineffective Coping related to effects of acute illness and major changes in lifestyle

For the patient experiencing an MI, additional problems include:

1. Potential for dysrhythmias
2. Potential for heart failure

3. Potential for recurrent symptoms and extension of injury

PLANNING AND IMPLEMENTATION

Astute assessment skills, timely analysis of troponin, and analysis of the 12-lead ECG (or 18-lead ECG for a suspected right ventricular infarction) are essential to ensure appropriate patient care management. This is particularly important since the average time a patient waits before seeking treatment is 2 hours and 20 minutes. This delay lessens the 4- to 6-hour window of opportunity for the most advantageous treatment with percutaneous intervention.

Managing Acute Pain

Patients with *diabetes mellitus* and coronary artery disease (CAD) may not experience chest pain or pressure because of diabetic neuropathy. In this patient population, the onset of acute myocardial infarction (AMI) may be signaled by new onset of atrial fibrillation. With new-onset atrial fibrillation, a cardiac workup should be done to rule out myocardial infarction.

Planning: Expected Outcomes. The expected outcome is that the patient will verbalize a report of decreased pain and discomfort as a result of prompt collaborative interventions.

Interventions. The purpose of patient-centered collaborative care is to eliminate discomfort by providing pain relief measures, decreasing myocardial oxygen demand, and increasing myocardial oxygen supply.

Emergency Care. Evaluate any report of pain, obtain vital signs, ensure an IV access, and notify the health care provider of the patient's condition. [Chart 40-3](#) summarizes the emergency interventions for the patient with symptoms of CAD.

Pain relief helps increase the oxygen supply and decrease myocardial oxygen demand. The American Heart Association (AHA) recommends several pain management strategies, including morphine sulfate and oxygen. *Give morphine as the priority in managing pain in patients having an MI!*

Drug Therapy. At home or in the hospital, the patient may take nitroglycerin to relieve episodic anginal pain.

CHART 40-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with Chest Discomfort

- Assess airway, breathing, and circulation (ABCs). Defibrillate as needed.
- **Provide continuous ECG monitoring.**
- Obtain the patient's description of pain or discomfort.
- Obtain the patient's vital signs (blood pressure, pulse, respiration).
- Assess/provide vascular access.
- Consult chest pain protocol or notify the physician or Rapid Response Team for specific intervention.
- Obtain a 12-lead ECG within 10 minutes of reports of chest pain.
- Provide pain relief medication and aspirin as prescribed.
- Administer oxygen therapy to maintain oxygen saturation $\geq 95\%$.
- Remain calm. Stay with the patient if possible.
- Assess the patient's vital signs and intensity of pain 5 minutes after administration of medication.
- Remedicate with prescribed drugs (if vital signs remain stable), and check the patient every 5 minutes.
- Notify the physician if vital signs deteriorate.

Aspirin 325 mg, an antiplatelet drug, may also be taken daily to prevent clots that further block coronary arteries.

Nitroglycerin (NTG), a nitrate often referred to as “nitro,” increases collateral blood flow, redistributes blood flow toward the subendocardium, and dilates the coronary arteries. In addition, it decreases myocardial oxygen demand by peripheral vasodilation, which decreases both preload and afterload. Teach the patient to hold the tablet under the tongue and drink 5 mL of water, if necessary, to allow the tablet to dissolve. NTG spray is also available and is more quickly absorbed. Pain relief should begin within 1 to 2 minutes and should be clearly evident in 3 to 5 minutes. After 5 minutes, recheck the patient’s pain intensity and vital signs. If the BP is less than 100 mm Hg systolic or 25 mm Hg lower than the previous reading, lower the head of the bed and notify the health care provider. If the patient is experiencing some but not complete relief and vital signs remain stable, another NTG tablet or spray may be used. In 5-minute increments, a total of three doses may be administered in an attempt to relieve angina pain. If the patient uses NTG spray instead of the tablet, teach him or her to sit upright and spray the dose under the tongue. NTG topical patches should be placed below the nipple line to decrease discomfort.

Angina usually responds to NTG. The patient typically states that the pain is relieved or markedly diminished. When simple measures, such as taking three sublingual nitroglycerin tablets one after the other, do not relieve chest discomfort, the patient may be experiencing an MI.

! NURSING SAFETY PRIORITY

Critical Rescue

If the patient is experiencing an MI, prepare the patient for transfer to a specialized unit where close monitoring and appropriate management can be provided. If the patient is at home or in the community, call 911 for transfer to the closest emergency department.

In a specialized unit, the health care provider may prescribe IV NTG for management of the chest pain. Begin the drug infusion slowly, checking the BP and pain level every 3 to 5 minutes. The nitroglycerin dose is increased until the pain is relieved, the BP falls excessively, or the maximum prescribed dose is reached (**Chart 40-4**).

When pain or other symptoms have subsided and the patient is stabilized, the health care provider may change the drug to an oral or topical nitrate. During administration of long-term oral and topical nitrates, an 8- to 12-hour nitrate-free period should be maintained to prevent tolerance. The patient may initially report a headache. Give acetaminophen (Tylenol, Exdol ) before the nitrate to ease some of this discomfort.

The health care provider usually prescribes *morphine sulfate (MS)* to relieve discomfort that is unresponsive to nitroglycerin. Morphine relieves MI pain, decreases myocardial oxygen demand, relaxes smooth muscle, and reduces circulating catecholamines. It is usually administered in 2- to 10-mg doses IV every 5 to 15 minutes until the maximum prescribed dose is reached or the patient experiences relief or signs of toxicity. Monitor for adverse effects of morphine, which include respiratory depression, hypotension, bradycardia, and severe vomiting. Treatment for morphine toxicity is

naloxone (Narcan) 0.2 to 0.8 mg IV, vasopressor drugs, IV fluids, and oxygen therapy. Monitor the patient’s vital signs and cardiac rhythm every few minutes.

These strategies are often enough to relieve the pain. If they are not adequate, additional interventions identified in the Improving Cardiopulmonary Tissue Perfusion section below may be attempted.

Other Interventions. Several other interventions may be used with drug therapy to relieve chest pain. Supplemental oxygen increases the amount of oxygen available to myocardial tissue. Therefore oxygen is often prescribed and administered at a flow of 2 to 4 L/min by nasal cannula titrated to maintain an arterial oxygen saturation (SaO_2) of 95% or higher. If the BP is stable, assist the patient in assuming any position of comfort. Placing the patient in semi-Fowler’s position often enhances comfort and tissue oxygenation. A quiet, calm environment and explanations of interventions often reduce anxiety and help relieve chest pain. If needed, remind the patient to take several deep breaths to increase oxygenation.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice; Informatics

A 77-year-old man living at home had chest pain after awakening from a nap. He called his only daughter, who was not home; he then called 911 and was taken to the emergency department (ED).

1. As his ED nurse, what is your first action in response to his report of chest pain? What evidence supports this decision?
2. The physician prescribes IV morphine for pain. For what adverse effects will you monitor during and after morphine administration?
3. What other drugs might the physician prescribe at this time and why?
4. What will you tell his daughter about his condition?
5. What will you document about this patient’s care?

Improving Cardiopulmonary Tissue Perfusion

Planning: Expected Outcomes. The primary outcome is that the patient will have increased myocardial perfusion as evidenced by an adequate cardiac output, normal sinus rhythm, and vital signs within normal limits.

Interventions. Because myocardial infarction (MI) is a dynamic process, restoring perfusion to the injured area (usually within 4 to 6 hours) often limits the amount of extension and improves left ventricular function. Complete, sustained reperfusion of coronary arteries in the first few hours after an MI has decreased mortality rates.

Drug Therapy. *Aspirin (ASA)* therapy is recommended by the American College of Cardiology and the American Heart Association (AHA). It inhibits both platelet aggregation and vasoconstriction, thereby decreasing the likelihood of thrombosis. *If the patient has new-onset angina at home, teach him or her to chew aspirin 325 mg (4 “baby aspirins” that are 81 mg each) immediately and call 911!* The antiplatelet effect of ASA begins within 1 hour of use and continues for several days. Administer 162 to 325 mg non-enteric-coated aspirin every day to all patients with suspected CAD unless absolutely contraindicated. Instruct the patient to chew and swallow the drug and continue taking the drug unless adverse effects occur.

CHART 40-4 COMMON EXAMPLES OF DRUG THERAPY

Coronary Artery Disease (Nitrates, Beta Blockers, and Antiplatelet Agents)

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Nitrates			
Nitroglycerin (Nitrostat, NitroQuick)	0.3-0.4 mg sublingually every 5 min; up to 3 tablets over 15 min	Instruct patients to lie down with the head of the bed at a level of comfort when taking the sublingual form.	Hypotension can be dramatic, immediate, and intensified by the upright position.
Nitrolingual translingual spray	0.4 mg/metered spray	Monitor BP. Pay attention to orthostatic changes. Instruct patients to allow the sublingual tablet to dissolve and to avoid swallowing the tablet. Check the expiration date on sublingual tablets and sprays. Tablets should be replaced every 3-5 mo. Determine whether pain is relieved. Monitor for headache. Do not administer to patients taking drugs used to treat sexual dysfunction (e.g., sildenafil, tadalafil, vardenafil).	A decrease in BP occurs with vasodilation. The sublingual dose is absorbed through the sublingual mucous membranes. The efficacy of the tablets decreases with time. Additional medication may be required to relieve pain. Vasodilation is generalized. Very serious (possibly fatal) interactions may occur.
Isosorbide dinitrate (Isordil, Iso-Bid)	2.5 mg sublingually every 4-6 hr; 5-40 mg orally four times daily 40-80 mg sustained-release tablet every 8-12 hr	Instruct patients taking sublingual forms to lie down before administration. Monitor BP, and assess for dizziness.	The hypotensive effect can be dramatic and immediate with sublingual administration. A decrease in BP occurs with vasodilation.
Isosorbide mononitrate (Imdur)	60-mg extended-release tablet daily	Schedule sustained-release form with an 8- to 12-hr dose-free interval.	Tolerance may develop.
Nitroglycerin patch (Minitran, Nitro-Dur, Nitrek)	Transdermally started at 5 mg/24 hr (10-cm ² system)	Remove the patch from the patient before defibrillation. Rotate application sites. Apply the patch to a clean, dry, hairless area. Remove patch after 12-14 hr each day.	The patient may develop a burn. Rotation prevents skin irritation. The drug is better absorbed when the skin is clean, dry, and hairless. Removal prevents drug tolerance.
Beta Blockers			
Carvedilol (Coreg, Corg CR)	12.5-25 mg orally twice daily for Corg; 40-80 mg orally once daily for Corg CR	Assess heart rate before administration. Monitor BP. Observe for signs of heart failure. Assess for shortness of breath and wheezing.	Beta-blocking effects cause a decrease in heart rate. The hypotensive effect is due to a decrease in cardiac output, suppressed renin activity, and beta-blocking effects. Heart failure may occur as a result of a decrease in cardiac output. Beta ₂ -blocking effects in the lungs can cause bronchoconstriction.
Metoprolol (Lopressor, Toprol XL, Betaloc  , a cardioselective beta-adrenergic blocker)	<i>Angina:</i> 25-100 mg orally daily <i>MI:</i> 100 mg orally twice daily; 5 mg IV over 2 min may be repeated twice for a total of 15 mg	Assess heart rate before administration; do not administer if heart rate <50-60 beats/min. Monitor BP, and hold for systolic <90-100 mm Hg. Assess patients for cough, shortness of breath, edema, and weight gain.	Beta blockers may cause further decreases in heart rate. Decreased BP pressure is an anticipated effect. These are indications of heart failure.
Antiplatelet Agents			
Aspirin (Empirin, Apo-ASA  , Ecotrin)	81-325 mg orally daily	Suggest that patients take the daily dose with food. Question patients about ringing in the ears. Emphasize to patients that aspirin is an important cardiac medication and should be continued unless they are told to stop.	Gastric irritation may occur. Tinnitus may occur with aspirin toxicity. Studies document significantly better survival rates for patients with coronary artery disease receiving aspirin.
Thienopyridines			
Clopidogrel (Plavix) Do not confuse Plavix with Paxil	<i>Recent MI:</i> 75 mg orally daily <i>Acute coronary syndrome:</i> 300-600 mg orally, then 75-150 mg daily	Teach patients to take drug with food. Inform patients to report any usual bleeding or bruising.	Drug can cause diarrhea and other GI disturbances. Drug prevents platelet aggregation, thus slowing down clot formation.
Prasugrel (Effient)	<i>Acute coronary syndrome:</i> 60 orally mg, then 10 mg daily	Inform patients to report any usual bleeding or bruising.	Contraindicated in patients with history of prior stroke or >75 yrs of age, due to increased risk for bleeding. If patient <60 kg, consider lowering dose to 5 mg daily.

! NURSING SAFETY PRIORITY**Drug Alert**

For patients taking aspirin every day, observe for bleeding tendencies, such as nosebleeds or blood in the stool. Aspirin should be discontinued if bleeding occurs.

Glycoprotein (GP) IIb/IIIa inhibitors target the platelet component of the thrombus. Abciximab (ReoPro), eptifibatide (Integrilin), or tirofiban (Aggrastat) is administered IV to prevent fibrinogen from attaching to activated platelets at the site of a thrombus. These medications are used in acute coronary syndromes (especially unstable angina, NSTEMI, and non-Q-wave MI). They are also given before and during percutaneous transluminal coronary angioplasty (PTCA) to maintain patency of an artery with a large clot and are given with fibrinolytic agents after MI. If the GP IIb/IIIa inhibitors are used with a fibrinolytic agent, the dose of the thrombolytic is reduced by 25% to 50% to decrease the risk for bleeding.

! NURSING SAFETY PRIORITY**Drug Alert**

When giving GP IIb/IIIa inhibitors, assess the patient closely for bleeding or hypersensitivity reactions. If either occurs, notify the health care provider or Rapid Response Team immediately.

Once-a-day *beta-adrenergic blocking agents* (e.g., metoprolol XL [Toprol XL], carvedilol CR [Coreg CR]), sometimes just called *beta blockers* (BBs), decrease the size of the infarct, the occurrence of ventricular dysrhythmias, and mortality rates in patients with MI. The physician usually prescribes a cardioselective beta-blocking agent within the first 1 to 2 hours after an MI if the patient is hemodynamically stable. Beta blockers slow the heart rate and decrease the force of cardiac contraction (see [Chart 40-4](#)). Thus these agents prolong the period of diastole and increase myocardial perfusion while reducing the force of myocardial contraction. With beta blockade, the heart can perform more work without ischemia. During beta-blocking therapy, monitor for:

- Bradycardia
- Hypotension
- Decreased level of consciousness (LOC)
- Chest discomfort

Assess the lungs for crackles (indicative of heart failure) and wheezes (indicative of bronchospasm). Hypoglycemia, depression, nightmares, and forgetfulness are also problems with beta blockade, especially in older patients. Many of these side effects decrease with time.

! NURSING SAFETY PRIORITY**Drug Alert**

Do not give beta blockers if the pulse is below 60 or the systolic BP is below 100 without first checking with the health care provider.

Health care providers frequently prescribe *angiotensin-converting enzyme (ACE) inhibitors* or *angiotensin receptor blockers (ARBs)* within 48 hours of an MI to prevent

ventricular remodeling and the development of heart failure. Both ACE inhibitors and ARBs increase survival after an MI. Monitor the patient for decreased urine output, hypotension, and cough. Check for changes in serum potassium, creatinine, and blood urea nitrogen. ([Chapter 38](#) provides a more detailed discussion of ACE inhibitors and ARBs.)

For patients with angina, the health care provider may prescribe calcium channel blockers to promote vasodilation and myocardial perfusion. These drugs are indicated for patients with variant angina or for those who are hypertensive and continue to have angina despite therapy with beta blockers (unstable angina). They are *not* indicated after an MI. Monitor the patient for hypotension and peripheral edema, and review the frequency of angina episodes.

Calcium channel blockers are also used for chronic stable angina (CSA). When they are not successful in managing CSA, *ranolazine (Ranexa)* may be added to the drug regimen. This drug has anti-angina and anti-ischemic properties and is often effective in relieving the pain associated with CSA.

Reperfusion Therapy. As time passes, myocardial tissue can become increasingly ischemic and necrotic. Therefore, based on the location and skill set of the health care institution, one of two reperfusion strategies should be employed to open a blocked artery in a patient experiencing AMI.

Thrombolytic therapy using **fibrinolytics** dissolves thrombi in the coronary arteries and restores myocardial blood flow. Examples of these agents, which target the fibrin component of the coronary thrombosis, include:

- Tissue plasminogen activator (t-PA, alteplase [Activase]) (IV or intracoronary)
- Reteplase (Retavase) (IV or intracoronary)
- Tenecteplase (TNK) (IV push [IVP])

Intracoronary fibrinolytics may be delivered during cardiac catheterization. Thrombolytic agents are most effective when administered within the first 6 hours of a coronary event. They are used in men and women, young and old.

Thrombolytic therapy is given in a unit where the patient can be continuously monitored. It is indicated for chest pain of longer than 30 minutes' duration that is unrelieved by nitroglycerin, with indications of transmural ischemia and injury as shown by the ECG. Contraindications include recent abdominal surgery or stroke, because bleeding may occur when fresh clots are lysed (broken down or dissolved). [Table 40-2](#) lists the current contraindications to thrombolytic therapy.

Patients who weigh less than 143 pounds (65 kg) may need to have their dose of thrombolytic adjusted to lessen the likelihood of bleeding.

! NURSING SAFETY PRIORITY**Drug Alert**

During and after thrombolytic administration, immediately report any indications of bleeding to the health care provider or Rapid Response Team. Observe for signs of bleeding by:

- Documenting the patient's neurologic status (in case of intracranial bleeding)
- Observing all IV sites for bleeding and patency
- Monitoring clotting studies
- Observing for signs of internal bleeding (Monitor hemoglobin, hematocrit, and blood pressure.)
- Testing stools, urine, and emesis for occult blood

TABLE 40-2 CONTRAINDICATIONS TO THROMBOLYTIC THERAPY**Absolute**

- Any prior intracranial hemorrhage
- Known structural cerebral vascular lesion (e.g., arteriovenous malformations)
- Known malignant intracranial neoplasm (primary or metastatic)
- Ischemic stroke within 3 months EXCEPT acute ischemic stroke within 3 hours
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head or facial trauma within 3 months

Relative

- History of chronic, severe, poorly controlled hypertension
- Severe uncontrolled hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)*
- History of prior ischemic stroke within 3 months, dementia, or known intracranial pathology not covered in contraindications
- Traumatic or prolonged (≥10 minutes) CPR or major surgery (within 3 weeks)
- Recent (within 2-4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase/anistreplase: prior exposure (>5 days ago) or prior allergic reaction to these agents
- Pregnancy
- Active peptic ulcer
- Current use of anticoagulants; the higher the INR, the higher risk for bleeding

CPR, Cardiopulmonary resuscitation; DBP, diastolic blood pressure; INR, international normalized ratio; MI, myocardial infarction; SBP, systolic blood pressure.

*Could be an absolute contraindication in low-risk patients with MI.

For some patients having an MI, primary **percutaneous transluminal coronary angioplasty (PTCA)** with stent (metallic mesh) placement may be used to reopen the clotted coronary artery. Percutaneous intervention has been associated with excellent return of blood flow through the coronary artery when it can be performed by an interventional cardiologist within 2 to 3 hours of the onset of symptoms. Many community hospitals can now perform emergent PTCA. When primary PTCA is not available, patients should receive immediate thrombolytic agents if they are appropriate candidates and then be transferred to a facility that can perform PTCA. This procedure is described in detail on p. 844 of this chapter.

Patients who receive fibrinolytics require PTCA for more definitive treatment such as stent placement. Therefore, if criteria for PTCA are met, it is more advantageous to go directly to the catheterization laboratory where definitive treatment, not just clot resolution, can be performed.

Monitor the patient for indications that the clot has been lysed (dissolved) and the artery reperfused. These indications include:

- Abrupt cessation of pain or discomfort
- Sudden onset of ventricular dysrhythmias
- Resolution of ST-segment depression/elevation or T-wave inversion
- A peak at 12 hours of markers of myocardial damage

After clot lysis with thrombolytics, large amounts of thrombin are released into the system, increasing the risk for vessel reocclusion. To maintain the patency of the coronary artery after thrombolytic therapy, the health care provider usually prescribes aspirin and IV heparin. Maintain the heparin

infusion for 3 to 5 days as prescribed, and monitor the activated partial thromboplastin time (aPTT). The target aPTT range is usually $1\frac{1}{2}$ to $2\frac{1}{2}$ times the control sample. The heparin antifactor Xa assay (heparin assay) test may be used instead of the aPTT in some clinical facilities. Low-molecular-weight heparin (LMWH) (enoxaparin [Lovenox]) may be substituted for IV heparin. Therapeutic dosing of LMWH in this patient population should be based on weight (1 mg/kg).

**NCLEX EXAMINATION CHALLENGE****Physiological Integrity**

A client who had thrombolytic therapy is receiving a continuous infusion of sodium heparin. In the past hour, the client's blood pressure changed from 122/74 to 98/46 mm Hg. His pulse is rapid and weak. What is the nurse's first action at this time?

- A. Assess for signs of bleeding.
- B. Slow the heparin infusion rate.
- C. Document the blood pressure change.
- D. Stop the heparin infusion immediately.

Increasing Activity Tolerance

Planning: Expected Outcomes. The patient is expected to increase activity without chest pain and the need for supplemental oxygen as a result of a collaborative cardiac rehabilitation program.

Interventions. Activity intolerance is reduced by a planned program of cardiac rehabilitation implemented primarily by the nurse and physical therapist and continued after discharge.

Cardiac rehabilitation is the process of actively assisting the patient with cardiac disease in achieving and maintaining a vital and productive life while remaining within the limits of the heart's ability to respond to increases in activity and stress. It can be divided into three phases. *Phase 1* begins with the acute illness and ends with discharge from the hospital. *Phase 2* begins after discharge and continues through convalescence at home. *Phase 3* refers to long-term conditioning.

In the acute phase (phase 1), promote rest and ensure limited mobility. Assistance may be needed for some ADLs, such as ambulation to the bathroom. Patients progress at their own rate to increasing levels of activity depending on their clinical status, age, and physical capabilities.

The next step in phase 1 is independent ambulation of the patient in the room and to the bathroom. Encourage progressive ambulation in the hallway, usually 50, 100, and then 200 feet three times a day. In addition, the patient may begin showering for 5 or 10 minutes with warm water. A chair should be available to facilitate rest and maintain balance.

**NURSING SAFETY PRIORITY****Action Alert**

During cardiac rehabilitation, assess the patient's heart rate, blood pressure (BP), respiratory rate, and level of fatigue with each higher level of activity. Decreases greater than 20 mm Hg in the systolic BP, changes of 20 beats per minute in the pulse rate, and reports of dyspnea or chest pain indicate intolerance of activity. If these manifestations develop, notify the health care provider and do not advance the patient to the next level. Older adults with CAD often have needs and concerns different from those of younger adults, as described in Chart 40-5.

CHART 40-5 NURSING FOCUS ON THE OLDER ADULT

Coronary Artery Disease

- Recognize that chest pain may not be evident in the older patient. Examples of associated symptoms are unexplained dyspnea, confusion, or GI symptoms.
- Although older adults have a greater reduction in mortality rate from myocardial infarction (MI) with the use of thrombolytics, they also have the most severe side effects. Monitor older patients receiving thrombolytics extremely carefully.
- Dysrhythmia may be a normal age-related change rather than a complication of MI. Determine whether the dysrhythmia is causing significant symptoms. Then notify the physician.
- If beta blockers are used, assess the patient carefully for the development of side effects. Exacerbation of the depression some older adults have is a significant problem with beta blockade.
- Plan slow, steady increases in activity. Older adults with minimal previous exercise show particular benefit from a gradual increase in activity.
- Older adults should plan longer warm-up and cool-down periods when participating in an exercise program. Their pulse rates may not return to baseline until 30 minutes or longer after exercise.

All patients with AMI should be referred to a phase 2 cardiac rehabilitation program upon discharge from the hospital. Collaborate with the case manager to plan for the patient's continuing care.

Promoting Effective Coping

Planning: Expected Outcomes. The patient is expected to learn to cope with the cardiac event and identify effective coping strategies with the help of support systems.

Interventions. Assess the patient's level of anxiety while allowing expressions of any apprehension, and attempt to define its origin. Simple, repeated explanations of therapies, expectations, and surroundings, as well as patient progress, may help relieve anxiety.

Identify the patient's current *coping* mechanisms. The most common are denial, anger, and depression. Denial allows the patient to decrease a threat and use problem-focused coping mechanisms. The patient may avoid discussing what has happened and yet comply with treatment regimens. This type of denial decreases anxiety and should not be discouraged. *However, denial that results in a patient who refuses to follow treatment regimens can be harmful.* Because this behavior is usually due to extreme anxiety or fear, threats only worsen the behavior. Remain calm, and avoid confronting the patient. Clearly indicate when a behavior is not acceptable and is potentially harmful as a result of noncompliance.

Anger may represent an attempt to regain control of life. Encourage the patient to verbalize the source of frustration, and provide opportunities for decision making and control. Collaborate with the certified spiritual chaplain in the hospital to help the patient cope with the situation. Help the patient identify support systems, such as family, friends, church, or social group.

Depression may be a response to grief and loss of function. Listen as the patient verbalizes feelings of loss, being careful not to offer false or general reassurances. Acknowledge depression, but encourage the patient to perform ADLs and other activities within restrictions.

Identifying and Managing Dysrhythmias

Planning: Expected Outcomes. The most desired outcome for the patient is that he or she will be free of dysrhythmias. If they occur, they will be identified and managed early to prevent complications or death.

Interventions. *Dysrhythmias are the leading cause of pre-hospital death in most patients with myocardial infarction (MI).* Even in the early period of hospitalization, most patients with MI experience some abnormal cardiac rhythm. When a dysrhythmia develops:

- Identify the dysrhythmia.
- Assess hemodynamic status.
- Evaluate for discomfort.

Dysrhythmias are treated when they cause hemodynamic compromise, increase myocardial oxygen requirements, or predispose the patient to lethal ventricular dysrhythmias.

Typical dysrhythmias for the patient with an *inferior* MI are bradycardias and second-degree AV blocks resulting from ischemia of the AV node. These rhythms tend to be intermittent. Monitor the cardiac rhythm and rate and the hemodynamic status. If the patient becomes hemodynamically unstable, a temporary pacemaker may be necessary.

The patient with an *anterior* MI is likely to exhibit premature ventricular contractions (PVCs) caused by ventricular irritability. Third-degree or bundle branch block is a serious complication in this patient because it indicates that a large portion of the left ventricle is involved. The health care provider may insert a pacemaker. Observe the patient closely to detect the development of heart failure. Appropriate interventions for dysrhythmias are described in [Chapter 36](#).

Monitoring for and Managing Heart Failure

Planning: Expected Outcomes. The most desired outcome for the patient is that he or she will be free of heart failure. However, if it occurs, the outcome is that the heart failure will be identified and treated early to prevent further complications.

Interventions. Decreased cardiac output related to heart failure is a relatively common complication after an MI resulting from left ventricular dysfunction, rupture of the intraventricular septum, papillary muscle rupture with valvular dysfunction, or right ventricular infarction. The most severe form of heart failure, *cardiogenic shock*, discussed later in this chapter, accounts for most in-hospital deaths after an MI. The type of management used to increase cardiac output depends on the location of the MI and the type of heart failure that resulted from the infarction.

Managing Left Ventricular Failure. When a patient with MI experiences damage to the left ventricle, rupture of the intraventricular septum, or tear of a papillary muscle, the amount of blood that the heart can eject is reduced. When volume and pressure are markedly increased in the pulmonary vasculature, pulmonary complications develop.

Nursing Assessment and Monitoring. Assess for manifestations of left ventricular failure and pulmonary edema by listening for crackles and identifying their location in the lung fields. Wheezing, tachypnea, and frothy sputum may also occur with pulmonary edema. Auscultate the heart, paying particular attention to the presence of an S₃ heart sound.

Monitor for these signs of inadequate organ *perfusion* that may result from decreased cardiac output:

- A change in orientation or mental status
- Urine output less than 30 mL/hr
- Cool, clammy extremities with decreased or absent pulses
- Unusual fatigue
- Recurrent chest pain

In specialized units, hemodynamic monitoring requiring the insertion of a pulmonary artery catheter may be started to assess the patient's preload, afterload, and cardiac output. Obtain and record hemodynamic measurements, which include:

- Right atrial pressure
- Pulmonary artery systolic and diastolic pressures
- Pulmonary artery wedge pressure (PAWP) (a measure of preload)
- Pulmonary vascular resistance
- Systemic vascular resistance (a measure of afterload)
- Cardiac output
- Central venous pressure (CVP)
- Cardiac index

Single values of these measurements are less significant than the trend of values combined with the patient's clinical manifestations. They help health care providers identify heart failure and guide the administration of fluids and vasoactive drugs. Chapter 35 describes hemodynamic monitoring in more detail.

Classification of Post-Myocardial Infarction Heart Failure.

Several classification systems may be used to categorize heart failure after an MI. For example, the Killip system identifies four classes based on prognosis (Table 40-3) (Siniorakis, et al., 2000). This system complements the ACC/AHA heart failure classification of function assessment discussed in Chapter 37.

Patients with *class I* heart failure often respond well to reduction in preload with IV nitrates and diuretics. Monitor the urine output hourly, check vital signs hourly, continue to assess for signs of heart failure, and review the serum potassium level.

Patients with *class II* and *class III* heart failure may require diuresis and more aggressive medical intervention, such as afterload reduction and/or enhancement of contractility. IV nitroprusside or nitroglycerin may be used to decrease both preload and afterload. These drugs are given as continuous infusions in specialized units where the PAWP and BP can be closely monitored. The BP can drop in response to excessive vasodilation.

Patients in *classes II* and *III* are usually started on once-a-day beta blockers (usually Toprol XR or Coreg CR). Dosing is titrated depending on goal achievement and drug tolerance. Other drugs, including ACE inhibitors and ARBs, are

commonly prescribed to promote ventricular remodeling. These drugs are described in Chart 40-4 and in Chapters 37 and 38.

Positive inotropes, such as dobutamine (Dobutrex) and milrinone (Primacor), increase the force of cardiac contraction. They are administered by continuous IV infusion. The effects of these drugs on the blood vessels and heart rate vary and may be dose dependent. The infusions are titrated to promote cardiac output.

NURSING SAFETY PRIORITY

Drug Alert

Use caution when giving positive inotropes because of the potential risk for increasing myocardial oxygen consumption and further decreasing cardiac output. Monitor the patient frequently, paying particular attention to the development of chest pain.

Class IV heart failure is cardiogenic shock. In **cardiogenic shock**, necrosis of more than 40% of the left ventricle occurs. Most patients have a stuttering pattern of chest pain, resulting in piecemeal extension of the MI.

NURSING SAFETY PRIORITY

Critical Rescue

Monitor for, report, and document manifestations of cardiogenic shock immediately. These signs and symptoms include:

- Tachycardia
- Hypotension
- BP less than 90 mm Hg or 30 mm Hg less than the patient's baseline
- Urine output less than 30 mL/hr
- Cold, clammy skin with poor peripheral pulses
- Agitation, restlessness, or confusion
- Pulmonary congestion
- Tachypnea
- Continuing chest discomfort

Early detection is essential because diagnosed cardiogenic shock has a high mortality rate!

Drug Therapy. Medical interventions aim to relieve pain and decrease myocardial oxygen requirements through preload and afterload reduction (see Chart 40-4 and Chart 40-6). The health care provider prescribes IV morphine, which is used to decrease pulmonary congestion and relieve pain. Oxygen is administered. Intubation and mechanical ventilation may be necessary.

Use the information gained from hemodynamic monitoring to titrate drug therapy. Preload reduction may be cautiously attempted with diuretics or nitroglycerin, as described for patients with Killip class III heart failure. (See Chapter 35 for a complete discussion of preload and afterload.) Monitor systolic pressure continuously because vasodilation may result in a further decline in BP. Vasopressors and positive inotropes may be used to maintain organ perfusion, but these drugs increase myocardial oxygen consumption and can worsen ischemia. Use extreme caution in giving drug therapy.

Intra-Aortic Balloon Pump. When patients do not respond to drug therapy with improved tissue perfusion, decreased workload of the heart, and increased cardiac contractility,

TABLE 40-3 KILLIP CLASSIFICATION OF HEART FAILURE

CLASS	DESCRIPTION
I	Absent crackles and S ₃
II	Crackles in the lower half of the lung fields and possible S ₃
III	Crackles more than halfway up the lung fields and frequent pulmonary edema
IV	Cardiogenic shock

CHART 40-6 COMMON EXAMPLES OF DRUG THERAPY

Commonly Used Intravenous Vasodilators and Inotropes

DRUG	USUAL DOSAGE	NURSING INTERVENTIONS	RATIONALES
Nitrates			
Nitroprusside sodium (Nipride, Nitropress)	IV only by infusion device Begin with 0.4-0.5 mcg/kg/min May increase gradually to 10 mcg/kg/min	Monitor BP every 2-5 min when initiating therapy. If BP drops excessively, elevate the legs, decrease the dose, and increase fluids per unit policy. Monitor PAWP, SVR, BP, heart rate, urine output frequently. Titrate medication to obtain the desired effect. Protect from light. Maintain dose at less than 3 mcg/kg/min if possible. In patients requiring doses higher than 3 mcg/kg/min for longer than 24-36 hr, monitor for metabolic acidosis, confusion, or hyperreflexia. Examine blood thiocyanate level.	This agent is a potent, rapidly reversible vasodilator acting on both peripheral venous and arterial musculature. BP may drop in 2 min. This agent is light sensitive. Doses higher than 3 mcg/kg/min are associated with thiocyanate or cyanide toxicity. These are indications of the toxic effects of cyanide.
Nitroglycerin (Tridil)	IV only by infusion device Begin with 5 mcg/kg/min and gradually increase in increments of 5 every 3-5 min If no response after 20 mcg/kg/min, increase by 10-20 mcg until desired response	Monitor BP every 1-3 min when initiating therapy. If BP drops excessively, elevate the legs and decrease the dose according to unit policies. Monitor RAP, PAWP, SVR, BP, heart rate, and urine output frequently. Titrate medication to obtain the desired effect. Intermittent administration of IV nitroglycerin should be considered. Monitor patients for headache.	This agent dilates coronary arteries. It is a more potent systemic vasodilator than an arterial vasodilator. BP may drop in 1 min. Tolerance may develop rapidly to nitroglycerin administered by continuous IV. Headache is a frequent side effect of initial nitroglycerin therapy.
Milrinone (Primacor)	IV bolus 50 mcg/kg given over 10 min; start infusion of 0.375-0.75 mcg/kg/min; reduce dose in renal impairment	Assess BP and pulse every 5 min. If BP drops 30 mm Hg, stop infusion and call health care provider. Monitor I&O and weight.	Hypotension is a common adverse effect. The drug causes diuresis.
Fenoldopam (Corlopam)	0.01-1.6 mcg/kg/min IV	Assess BP and pulse every 5 min, then every 1 hr x 2, then every 4 hr, or according to agency policy. Monitor I&O, and assess for signs of dehydration. Observe IV site for extravasation.	Same as for milrinone.
Sympathomimetics			
Dopamine (Intropin)	IV only by infusion device Starting dose 2-5 mcg/kg/min Titrate up to 50 mcg/kg/min	Determine the reason for use and the expected result. Observe the patient's heart rate, ECG, BP, PAWP, SVR, cardiac output, and urine output every 5 min to every 1 hr. Titrate the dose carefully to maintain the dose range and obtain the desired effect. Infuse through a central catheter.	This agent is a dose-dependent activator of alpha, beta, and dopaminergic receptors. 2-5 mcg/kg/min stimulates dopaminergic receptors, which promotes renal and mesenteric blood flow. 5 mcg/kg/min stimulates beta receptors. This increases heart rate and contractility more than 10-15 mcg/kg/min; alpha effects predominate. This causes peripheral constriction. Extravasation can cause tissue necrosis and sloughing. These are adverse effects.
Dobutamine (Dobutrex)	IV only by infusion device, 2-10 mcg/kg/min. May increase to 40 mcg/kg/min.	Monitor patients for ectopy and angina. Observe patients continuously during administration. Titrate the drug on the basis of adequate tissue perfusion: mentation, skin temperature, peripheral pulses, PAWP, cardiac output, SVR, and urine output. Monitor for atrial and ventricular ectopy.	This agent is a very strong beta ₁ -receptor activator and a moderately strong beta ₂ -activator. Dysrhythmias are an adverse effect.

BP, Blood pressure; ECG, electrocardiogram; I&O, input and output; PAWP, pulmonary artery wedge pressure; RAP, right atrial pressure; SVR, systemic vascular resistance.

an **intra-aortic balloon pump (IABP)** may be inserted. The IABP is an invasive intervention that is used to improve myocardial perfusion during an acute MI, reduce preload and afterload, and facilitate left ventricular ejection.

The health care provider can insert the device percutaneously or through a surgical cutdown. Inflation of the IABP during diastole augments the diastolic pressure and improves coronary perfusion by increasing blood flow to the arteries. Deflation of the balloon just before systole reduces afterload at the time of systolic contraction. This action facilitates emptying of the left ventricle and improves cardiac output. The balloon catheter is attached to a pump console, which is triggered by an ECG tracing and arterial waveform.

Percutaneous Ventricular Assist Device. In patients undergoing high-risk percutaneous transluminal coronary angioplasty (PTCA) or those at risk for cardiogenic shock, a percutaneous ventricular assist device may be used. These devices are temporary to decrease the myocardial workload and oxygen consumption of the heart and increase cardiac output and peripheral perfusion.

Immediate Reperfusion. Immediate reperfusion is an invasive intervention that shows some promise for managing cardiogenic shock. The patient is taken to the cardiac catheterization laboratory, and an emergency left-sided heart catheterization is performed. If he or she has a treatable occlusion or occlusions, the surgeon performs a percutaneous transluminal coronary angioplasty (with stent placement) in the catheterization laboratory or the patient is transferred to the operating suite for a coronary artery bypass graft (CABG).

Managing Right Ventricular Failure. Conditions other than left ventricular failure may result in decreased cardiac output after an MI. In about a third of patients with inferior MIs, right ventricular infarction and failure develop. In this instance, the right ventricle fails independently of the left. Decreased cardiac output with a paradoxical pulse, clear lungs, and jugular venous distention occurs when the patient is in semi-Fowler's position.

A right ventricular MI may be documented by echocardiography and by an ECG using right-sided precordial leads. The desired outcome of management is to improve right ventricular stroke volume by increasing right ventricular fiber stretch or preload. To enhance right ventricular preload, give sufficient fluids (as much as 200 mL/hr) to increase right atrial pressure to 20 mm Hg. *Monitor the pulmonary artery wedge pressure (PAWP)—attempting to maintain it below 15 to 20 mm Hg—and auscultate the lungs to assess for left-sided heart failure. If symptoms of this complication occur, notify the health care provider immediately.*

Monitoring for and Managing Recurrent Symptoms and Extension of Injury

Planning: Expected Outcomes. The most desired outcome is that the patient will not have recurrent symptoms or an extension of myocardial injury. If these problems occur, they will be identified and treated early to prevent further complications or death.

Interventions. *Recurrent discomfort despite medical therapy is one of the major indications for surgical management of CAD.* Patients who continue to have chest discomfort despite medical therapy or who have ischemia during a stress test may require invasive correction by PTCA or CABG to resolve

angina or prevent MI. Before invasive treatment, a left-sided cardiac catheterization with coronary angiogram is performed to document that the lesions are correctable and that left ventricular pump function is adequate.

Percutaneous Transluminal Coronary Angioplasty. **Percutaneous transluminal coronary angioplasty (PTCA)**, most commonly done before stent placement, is an invasive but nonsurgical technique. It is performed to reduce the frequency and severity of discomfort for patients with angina and to bridge patients to coronary artery bypass graft (CABG) surgery. Because of the artery's normal elasticity and "memory" to retain its original shape, the artery often re-occludes if a stent is not used as part of the procedure.

Patients who are most likely to benefit from PTCA have single- or double-vessel disease with discrete, proximal, non-calcified lesions (clots). This procedure often does not work for complex clots. When identifying which lesions are treatable with PTCA, the cardiologist considers the clot's complexity and location, as well as the amount of myocardium at risk. Although treating lesions located in the left main artery places a large amount of myocardial tissue at risk if the vessel closes quickly, these lesions are now being treated more with PTCA and stent placement. In the past, coronary artery bypass grafting (CABG) was the intervention used for these patients. PTCA may also be used for the patient with an evolving acute MI, either alone or with thrombolytic therapy or glycoprotein (GP) IIb/IIIa inhibitor, to reperfuse the damaged myocardium.

Before the procedure, the patient receives an initial dose of a thienopyridine (clopidogrel [Plavix]) or prasugrel [Effient]), antiplatelet drugs. If there are any concerns that the patient may require CABG, the thienopyridine is held until postprocedure. The inhibition of the platelets is permanent and increases the risk for postoperative bleeding. Patients should wait 5 (clopidogrel) to 7 (prasugrel) days after dosing with a thienopyridine before undergoing CABG. If the patient has received thrombolytic therapy, clopidogrel (Plavix) is the preferred thienopyridine. The physician performs the angioplasty under fluoroscopic guidance in the cardiac catheterization laboratory. A balloon-tipped catheter is introduced through a guidewire to the coronary artery occlusion. The physician activates a compressor that inflates the balloon to force the plaque against the vessel wall, thus dilating the wall, and reduces or eliminates the occluding clot. Balloon inflation may be repeated until angiography indicates a decrease in the stenosis (narrowing) to less than 50% of the vessel's diameter (Fig. 40-3).

During the procedure, the patient may receive boluses of IV heparin or a continuous infusion of bivalirudin (Angiomax). Heparin is used to maintain an elevated activated clotting time and prevent clotting on wires and catheters during the procedure. Heparin is discontinued before removal of the catheters. Bivalirudin (Angiomax) is a directed thrombin inhibitor and is frequently used as an alternative to IIb/IIIa inhibitors and heparin. Bivalirudin has a short half-life (25 minutes) and is less dependent on renal function. IV or intra-coronary nitroglycerin or diltiazem (Cardizem) is given to prevent coronary vasospasm. PTCA initially reopens the vessel in most appropriately selected patients. Within the first 24 hours, however, a small percentage of patients have re-stenosis. At 6 months, a larger number have one or more blockages.

FIG. 40-3 Percutaneous transluminal coronary angioplasty.

! NURSING SAFETY PRIORITY

Critical Rescue

After the PTCA, monitor for potential problems including acute closure of the vessel (causes chest pain), bleeding from the insertion site, and reaction to the contrast medium used in angiography. Also monitor for and document hypotension, hypokalemia, and dysrhythmias. Report any of these findings to the physician or Rapid Response Team immediately!

The health care provider usually prescribes a long-term nitrate and dual antiplatelet therapy with aspirin and a thienopyridine for patients after PTCA. A beta blocker and an ACE inhibitor or ARB are added for patients who have had primary angioplasty after an MI. Patients who do not receive a thienopyridine continue to have infusions of GP IIb/IIIa inhibitors during the initial hours after PTCA. Some may experience hypokalemia after the procedure and require careful monitoring and potassium supplements. The nursing interventions for patients receiving these drugs are described in [Chart 40-4](#). Provide careful explanations of drug therapy and any recommended lifestyle changes.

Other Procedures. Other techniques being used to ensure continued patency of the vessel are laser angioplasty (the laser breaks up the clot), atherectomy, and stents. **Atherectomy** devices can either excise and retrieve plaque or emulsify it. One of the advantages of this procedure is that it creates a less bulky vessel with better elastic recoil. **Stents** are expandable metal mesh devices that are used to maintain the patent lumen created by angioplasty or atherectomy. Bare metal or drug-eluting stents (DES) (drug-coated) may be used. By providing a supportive scaffold, these devices prevent closure of the vessel from arterial dissection or vasospasm. A thienopyridine and aspirin (antiplatelet agents) are prescribed for 12 months after a stent has been placed ([Moser & Riegel, 2008](#)). [Fig. 40-4](#) shows a stent positioned in a coronary artery.

Another procedure that may be performed is rheolytic thrombectomy (e.g., [AngioJet®](#), [Vortex®](#)), which uses low-pressure, high-speed saline jets to break up the clot. The [EndiCOR X-SIZER®](#) lances and aspirates a clot simultaneously.

FIG. 40-4 A coronary stent open after balloon inflation.

Injecting vascular endothelial growth factor (VEGF) during angioplasty has increased perfusion to the wall of the heart. Also, VEGF helps initiate new blood vessel growth and development, which results in increased blood supply to cardiac muscle.

Coronary Artery Bypass Graft Surgery. Over 500,000 **coronary artery bypass graft (CABG)** surgeries are performed in the United States each year. It is the most common type of cardiac surgery and the most common procedure for older adults. Almost half of all CABGs are done for patients older than 65 years ([AHA, 2010](#)). The occluded coronary arteries are bypassed with the patient's own venous or arterial blood vessels or synthetic grafts. *The internal mammary artery (IMA) is the current graft of choice because it has a 90% patency rate at 12 years after the procedure.*

CABG is indicated when patients do not respond to medical management of CAD or when disease progression is evident. Because of the development of drug-eluting stents (DESs), patients who previously had no option other than CABG have been able to have their vessels revascularized without surgery. The decision for surgery is based on the patient's symptoms and the results of cardiac catheterization. Candidates for surgery are patients who have:

- Angina with greater than 50% occlusion of the left main coronary artery that cannot be stented
- Unstable angina with severe two-vessel disease, moderate three-vessel disease, or small-vessel disease in which stents could not be introduced
- Ischemia with heart failure
- Acute MI with cardiogenic shock
- Signs of ischemia or impending MI after angiography or PTCA
- Valvular disease
- Coronary vessels unsuitable for PTCA

The vessels to be bypassed should have proximal clots blocking more than 70% of the vessel's diameter but with good distal runoff. Bypass of less occluded vessels may result in poor perfusion through the graft and early obstruction. CABG is most effective when adequate ventricular function remains and the ejection fraction is close to or greater than 50%. Patients with lower ejection fractions are subject to develop more complications.

For most patients, the risk is low and the benefits of bypass surgery are clear. Surgical treatment of CAD does not appear to affect the life span. Left ventricular function is the most important long-term indicator of survival. CABG improves the quality of life for most patients. Most are pain-free at 1 year after surgery and remain so at 5 years after the procedure. The percentage of patients experiencing some pain increases sharply after 5 years.

Preoperative Care. CABG surgery may be planned as an elective procedure or performed as an emergency. It may be done as a *traditional* operative technique or performed as a *minimally invasive surgical (MIS)* technique. Patients undergoing elective surgery are admitted on the morning of surgery. Preoperative preparations and teaching are completed during prehospitalization interviews. Teach patients that their drugs will be changed after surgery. Ensure that the necessary drugs have been administered before surgery.

Familiarize the patient and family with the cardiac surgical–critical care unit (sometimes referred to as the “open heart” unit), and prepare them for postoperative care. If the procedure is elective, demonstrate and have the patient return a demonstration of how to splint the chest incision, cough, deep breathe, and perform arm and leg exercises. Stress that:

- The patient should report any pain to the nursing staff.
- Most of the pain will be in the site where the vessel was harvested. (With the use of endovascular vessel harvesting [EVH] and one or two small incisions, the pain and edema are less than for previously performed procedures.)
- Analgesics will be given for pain.
- Coughing and deep breathing are essential to prevent pulmonary complications.

- Early ambulation is important to decrease the risk for venous thrombosis and possible embolism.

For the *traditional surgical procedure*, explain that the patient will have a sternal incision; possibly a large leg incision; one, two or three chest tubes; an indwelling urinary catheter; pace-maker wires; and hemodynamic monitoring. An endotracheal tube will be connected to a ventilator for several hours postoperatively. Tell the patient and family that the patient will not be able to talk while the endotracheal tube is in place. When describing the postoperative course, emphasize that close monitoring and the use of sophisticated equipment are standard treatment.

Preoperative anxiety is common. An appropriate nursing assessment should identify the level of anxiety and the coping methods patients have used successfully in the past. Some patients may find it helpful to define their fears. Common sources of fear include fear of the unknown, fear of bodily harm, and fear of death.

In elective procedures, patients may benefit from detailed information about the surgery. Others may feel overwhelmed by so much material. Some patients need to discuss their feelings in detail or describe the experiences of people they know who have undergone CABG. Assess patients' anxiety level and help them cope.

Operative Procedures. Coronary artery bypass surgery is performed with the patient under general anesthesia for both cardiopulmonary bypass and off-pump surgery. For the *traditional operative procedure*, the cardiac surgical team begins the procedure with a median sternotomy incision and visualization of the heart and great vessels. Another surgical team may begin harvesting the vein if it is to be used for the graft. Synthetic grafts may be used instead.

Cardiopulmonary bypass (CPB) is used to provide oxygenation, circulation, and hypothermia during induced cardiac arrest. Blood is diverted from the heart to the bypass machine, where it is heparinized, oxygenated, and returned to the circulation through a cannula placed in the ascending aortic arch or femoral artery (Fig. 40-5). During bypass, the patient's core temperature remains between 95° F (35° C) (cold cardioplegia) and normal temperature (warm

FIG. 40-5 Heart-lung bypass circuitry used during cardiopulmonary bypass.

cardioplegia). Although cooling decreases the rate of metabolism and demand for oxygen, keeping the heart “warm” decreases postoperative complications that were more common when cold cardioplegia was used. The heart is perfused with a potassium solution, which decreases myocardial oxygen consumption and causes the heart to stop during diastole. This process ensures a motionless operative field and prevents myocardial ischemia.

Once the heart is arrested, the grafting procedure can begin. The surgeon uses the internal mammary artery (IMA), a saphenous vein, and/or a radial artery to bypass blockages in the coronary arteries (Fig. 40-6). The distal end of the vessel graft is dissected and attached below the clot in the coronary artery. If the surgeon uses a venous graft or the radial artery, it is anastomosed (sutured) proximally to the aorta and distally to the coronary artery just beyond the occlusion, thus improving myocardial perfusion. After flow rates through the grafts are measured, the heart is rewarmed slowly. The cardioplegic solution is flushed from the heart. The heart regains its rate and rhythm, or it may be defibrillated to return it to a normal rhythm. When the procedure is completed, the patient may be rewarmed (if cold cardioplegia was used) and weaned from the bypass machine while the grafts are observed for patency and leakage. The surgeon may place atrial and ventricular pacemaker wires and mediastinal and pleural chest tubes. Finally, the surgeon closes the sternum with wire sutures.

Postoperative Care. After traditional surgery, the patient is transported to a post-open heart surgery unit and undergoes mechanical ventilation for 3 to 6 hours. He or she requires highly skilled nursing care from a nurse qualified to provide post-cardiac surgery care, including routine postoperative care described in Chapter 18. *Be sure to use sterile technique when changing sternal or donor-site dressings.*

Connect the mediastinal tubes to water seal drainage systems, and ground the epicardial pacer wires by connecting

them to the pacemaker generator. Monitor pulmonary artery and arterial pressures, as well as the heart rate and rhythm, which are displayed on a monitor.

Closely assess the patient for dysrhythmias, such as bradydysrhythmias, atrial fibrillation, or heart block. Manage symptomatic dysrhythmias according to unit protocol or the health care provider’s prescription. Hypoxemia and hypokalemia are frequent causes of ventricular dysrhythmias. If the patient has symptomatic bradydysrhythmias or heart block, turn on the pacemaker and adjust the pacemaker settings as prescribed. Monitor for, report, and document other complications of CABG, including:

- Fluid and electrolyte imbalance
- Hypotension
- Hypothermia
- Hypertension
- Bleeding
- Cardiac tamponade
- Decreased level of consciousness
- Anginal pain

Managing Fluid and Electrolyte Imbalance. *Assessing fluid and electrolyte balance is a high priority in the early postoperative period.* Edema is common. However, decisions concerning fluid administration are made on the basis of BP, pulmonary artery wedge pressure (PAWP), right atrial pressure, cardiac output, cardiac index, systemic vascular resistance, blood loss, and urine output. An experienced specialized nurse interprets the assessment findings and adjusts fluid administration on the basis of standing unit policies or specific prescription from the physician.

Serum electrolytes (especially calcium, magnesium, and potassium) may be decreased postoperatively and are monitored carefully. Because the serum potassium level can fluctuate dramatically, electrolyte levels are checked frequently, since imbalances can cause dysrhythmias. Potassium and magnesium depletions are common and may result from

FIG. 40-6 Two methods of coronary artery bypass grafting. The procedure used depends on the nature of the coronary artery disease, the condition of the vessels available for grafting, and the patient’s health status.

hemodilution or diuretic therapy. Calcium replacement is based on the *ionized* serum calcium. The desired potassium level is 4.0 mEq/L, and the magnesium level should be 2.2 mEq/L.

If the serum potassium level is decreased, the health care provider may prescribe IV potassium replacement. The dose of potassium given exceeds the usual recommended level of no more than 20 mEq of potassium per hour. For potassium replacement, as much as 40 to 80 mEq may be mixed in 100 mL of IV solution and given at a rate up to 40 mEq per hour. The drug must be given through a central catheter and controlled by an infusion pump. The patient is placed on a cardiac monitor for intense, focused nursing observation.

Managing Other Complications. *Hypotension* (systolic BP <90 mm Hg) is a major problem because it may result in the collapse of the coronary graft. Decreased preload (decreased PAWP) can result from hypovolemia or vasodilation. If the patient is hypovolemic, it might be appropriate to increase fluid administration or administer blood. The health care provider may manage the patient with volume replacement followed by vasopressor therapy to increase the BP. However, if hypotension is the result of left ventricular failure (increased PAWP), IV inotropes might be needed.

Hypothermia is a common problem after surgery. Although warm cardioplegia is now the usual operative procedure used, it is not uncommon for the body temperature to drift downward after the patient leaves the surgical suite. Monitor the body temperature, and institute rewarming procedures if the temperature drops below 96.8° F (36° C). Rewarming may be accomplished with warm blankets, lights, or thermal blankets. The danger of rewarming patients too quickly is that they may begin shivering, resulting in metabolic acidosis, increased myocardial oxygen consumption, and hypoxia. *To prevent shivering, rewarming should proceed at a rate no faster than 1.8° F (1° C) per hour. Discontinue the procedure when the body temperature approaches 98.6° F (37° C) and the patient's extremities feel warm.*

Hypothermia is a significant risk for the patient after CABG surgery because it promotes vasoconstriction and *hypertension*. Other factors contributing to hypertension in the CABG patient include CPB, drug therapy, and increased sympathetic nervous system activity.

After surgery, many patients experience hypertension (if hypertension is defined as a systolic BP >140 to 150 mm Hg). Hypertension is dangerous because increased pressure promotes leakage from suture lines and may cause bleeding. Afterload reducers such as nitroprusside (Nipride) or fenoldopam (Corlopam) may be given to decrease afterload, ease the workload of the heart, and prevent heart failure.

To access the IMA, the pleural space has to be entered and requires a pleural chest tube with the mediastinal tubes, making pulmonary assessment crucial. An autotransfusion of chest drainage to assist with volume management when 500 mL has accumulated or 4 hours has elapsed may be done, depending on the clinical pathway or the health care provider's protocol. Maintain the patency of the mediastinal and pleural chest tubes. One effective way of promoting chest tube drainage is to prevent a dependent loop from forming in the tubing.

If the patient is bleeding and the mediastinal tubes are not kept patent, fluid (blood) may accumulate around the heart. The myocardium is then compressed, and **cardiac tamponade** results. The fluid compresses the atria and ventricles, preventing them from filling adequately and thus reducing cardiac output.

! NURSING SAFETY PRIORITY

Critical Rescue

Assess for, document, and report manifestations of cardiac tamponade immediately, including:

- Sudden cessation of previously heavy mediastinal drainage
- Jugular venous distention but clear lung sounds
- Pulsus paradoxus (BP more than 10 mm Hg higher on expiration than on inspiration)
- An equalizing of PAWP and right atrial pressure
- Cardiovascular collapse

Prepare the patient for echocardiogram or chest x-ray to confirm the diagnosis. Pericardiocentesis (withdrawal of fluid from the pericardium via a large needle) may not be appropriate for tamponade after coronary artery bypass graft (CABG) because the blood in the pericardium may have clotted. Volume expansion and emergency sternotomy with drainage are the treatments of choice.

The patient may also demonstrate *changes in level of consciousness*, which may be permanent or transient (short-term). Transient changes related to anesthesia, cardiopulmonary bypass (CPB), air emboli, or hypothermia occur in many patients. Assess for neurologic deficits, which may include slowness to arouse, memory loss, and new-onset confusion.

Patients with transient (temporary) neurologic deficits usually return to baseline neurologic status within 4 to 8 hours. *Permanent* deficits associated with an intraoperative stroke may be manifested by:

- Abnormal pupillary response
- Failure to awaken from anesthesia
- Seizures
- Absence of sensory or motor function

! NURSING SAFETY PRIORITY

Action Alert

Bleeding after CABG surgery occurs to a limited extent in all patients. Measure mediastinal and pleural chest tube drainage at least hourly. Report drainage amounts over 150 mL per hour to the surgeon. Patients with internal mammary artery (IMA) grafts may have more chest drainage than those with saphenous vein grafts (from the leg).

! NURSING SAFETY PRIORITY

Action Alert

After a CABG, check the patient's neurologic status every 30 to 60 minutes until he or she has awakened from anesthesia. Then check every 2 to 4 hours or per agency policy.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client had a coronary artery bypass graft 2 days ago and has a new onset of atrial fibrillation. What diagnostic test will the nurse check that could explain this dysrhythmia?

- A. Arterial oxygen level
- B. Serum potassium
- C. Serum sodium
- D. Blood urea nitrogen

Managing Pain. Differentiate between *sternotomy pain*, which is expected after CABG, and *anginal pain*, which might indicate graft failure. Typical sternotomy pain is localized, does not radiate, and often becomes worse when the patient coughs or breathes deeply. He or she may describe the pain as sharp, aching, or burning. Pain may stimulate the sympathetic nervous system, which increases the heart rate and vascular resistance while decreasing cardiac output. Administer enough of the prescribed analgesic in adequate doses to control pain. During the process of weaning the patient from mechanical ventilation, however, it may be necessary to use short-acting analgesics and to limit pain medication because of the respiratory depressant effects of analgesia.

Transfer from the Special Care Unit. Mechanical ventilation is usually provided for 3 to 6 hours after surgery until the patient is breathing adequately and is hemodynamically stable. During the first day, the patient usually has pacemaker wires, hemodynamic monitoring lines, and mediastinal tubes removed. He or she is then transferred to an intermediate care unit. *All CABG patients, especially those with IMA grafts, are at high risk for atelectasis, the number-one complication. Encourage them to splint, cough, turn, and deep breathe to expectorate secretions. Early ambulation after surgery is essential.* Two hours after extubation (removal of the endotracheal tube), patients should be dangled as tolerated and turned side to side. Within 4 to 8 hours after extubation, help patients out of bed into a chair. By the first day after surgery, they should be out of bed in a chair and ambulating 25 to 100 feet three times a day as tolerated. Continue to monitor for decreased cardiac output, pain, dysrhythmias, decreased oxygen saturation, and infection during these activities.

NURSING SAFETY PRIORITY

Action Alert

Monitor the neurovascular status of the donor arm of patients whose radial artery was used as a graft in CABG. Assess the hand color, temperature, pulse (both ulnar and radial), and capillary refill every hour initially. In addition, check the fingertips, hand, and arm for sensation and mobility at least every 4 hours. IV nitroglycerin is often given for the first 24 hours postoperatively to promote vasodilation in the donor arm and therefore maintain circulation.

Many patients have supraventricular dysrhythmias (especially atrial fibrillation) during the postoperative period, usually on the second or third postoperative day. Examine the monitor pattern for atrial fibrillation. When auscultating the heart, listen for an irregular rhythm.

Sternal wound infections develop between 5 days and several weeks after surgery in a small number of patients and are responsible for increased costs and longer hospital stays. Be alert for **mediastinitis** (infection of the mediastinum) by observing for:

- Fever continuing beyond the first 4 days after CABG
- Instability (bogginess) of the sternum
- Redness, induration, swelling, or drainage from suture sites
- An increased white blood cell count

The health care provider may perform a needle biopsy to confirm a sternal infection. Surgical débridement, antibiotic wound irrigation, and IV antibiotics are usually indicated. If sternal osteomyelitis has developed, 4 to 6 weeks of IV antibiotics are required. Prophylactic use of mupirocin (Bactroban) intranasally may be prescribed to decrease the incidence of sternal wound infection.

Postpericardiotomy syndrome is a source of chest discomfort for some post-cardiac surgery patients. The syndrome is characterized by pericardial and pleural pain, pericarditis, a friction rub, an elevated temperature and white blood cell count, and dysrhythmias. Postpericardiotomy syndrome may occur days to weeks after surgery and seems to be associated with blood remaining in the pericardial sac. Observe for the development of pericardial or pleural pain. For most patients, the syndrome is mild and self-limiting. However, they may require treatment similar to that for pericarditis. Be prepared to detect acute cardiac (pericardial) tamponade (see Chapter 37).

Minimally Invasive Direct Coronary Artery Bypass. The **minimally invasive direct coronary artery bypass (MIDCAB)** (also known as “keyhole” surgery) may be indicated for patients with a lesion of the left anterior descending (LAD) artery. In one of the most common MIDCAB procedures, a 2-inch left thoracotomy incision is made and the fourth rib is removed. Then, the left internal mammary artery (IMA) is dissected and attached to the still-beating heart below the level of the lesion. Cardiopulmonary bypass (CPB) is not required.

After surgery, assess for chest pain and ECG changes (Q waves and ST-segment and T-wave changes in leads V₂ to V₆) because occlusion of the IMA graft occurs acutely in about 10% of patients. *If there is any question of acute graft closure, immediately notify the health care provider.* Patients tend to have more incisional pain after MIDCAB than after traditional CABG surgery, but the pain can usually be managed with oxycodone or codeine. *Because they have a thoracotomy incision and a chest tube or smaller-lumen vacuum chest device, patients are encouraged to cough, deep breathe, and use an incentive spirometer for a week postoperatively.* Most patients spend less than 6 hours in a critical care unit and are discharged in 2 or 3 days.

Endovascular (Endoscopic) Vessel Harvesting (EVH). Regardless of whether the traditional CABG or the MIDCAB is performed, the donor vessel may be obtained using an endoscope rather than a large surgical incision. The radial artery or a vein in the leg may be taken using this method. Instead of a large, painful incision, the patient has one or two very small incisions in the leg or arm. This procedure has decreased hospital length of stay, postoperative complications, and pain.

Transmyocardial Laser Revascularization. **Transmyocardial laser revascularization** is a procedure for patients with unstable angina and inoperable CAD with areas of reversible myocardial ischemia. After a single-lung intubation, a left anterior thoracotomy is performed and the heart is visualized. A laser is used to create 20 to 24 long, narrow channels through the left ventricular muscle to the left ventricle. These channels will eventually allow oxygenated blood to flow during diastole from the left ventricle to nourish the muscle. After surgery, the patient is transported to a critical care unit, where hemodynamic monitoring is used to assess for anginal episodes and bleeding disturbances.

Off-Pump Coronary Artery Bypass. Off-pump coronary artery bypass (OPCAB) is a procedure in which open heart surgery is performed without the use of a heart-lung bypass machine. Advantages include shorter hospital stays and decreased mortality rate, risk for infection, and cost. The disadvantage of OPCAB is that it requires cardiac surgeons to have increased skill to master the technique.

Robotic Heart Surgery. Robotic heart surgery is a new step toward less invasive open heart surgery. Surgeons operate endoscopically through very small incisions in the chest wall. Use of robotics provides surgeons with capabilities that simplify the surgical process, eliminates tremors that can exist with human hands, increases the ability to reach otherwise inaccessible sites, and improves depth perception and visual acuity.

Other advantages of robotic procedures include shorter hospital stays (average stay is 2 to 3 days), less pain because of smaller incisions, no need for heart-lung bypass machine, less anxiety for the patient, and greater patient acceptance. The use of robotics also allows surgeons to perform telesurgery, performing heart procedures over long distances.

Disadvantages include computer failure, limited numbers of surgeons skilled in these techniques, and the length of surgery time (the time is about 50 minutes longer than the conventional surgery).

Community-Based Care

Home Care Management

Case management is most appropriate for patients who meet high-cost, high-volume, and high-risk criteria. Patients with coronary artery disease (CAD) clearly meet all these criteria. Clinical pathways and case management programs for those with CAD are used in most U.S. hospitals. By focusing on cardiovascular risk reduction and improving the continuity of care, health care professionals have reduced the length and cost of hospital stays. Posthospital case management should reduce hospital readmission rates and improve patient health.

Patients who have experienced a myocardial infarction (MI), angina, or coronary artery bypass graft (CABG) surgery are usually discharged to home or to a transitional care setting with drug therapy and specific activity prescriptions. Depending on the procedure, hospital stays may be 3 to 5 days for patients with MI or those undergoing CABG and only 1 to 3 days for those undergoing percutaneous transluminal coronary angioplasty (PTCA) or newer surgeries. Therefore patients are still recovering when they are discharged from the hospital and need continuing care.

Patients should not be discharged to home alone. Assess whether the patient has family or friends to provide

assistance. In some cases, a home care nurse may be needed (Chart 40-7). Older adults are often living alone when coronary events occur and may have a greater need for home assistance after CABG surgery (Chart 40-8). A patient who was a resident in a long-term care facility may be returned there after hospitalization for unstable angina, MI, or CABG surgery.

CHART 40-7 HOME CARE ASSESSMENT

The Patient Who Has Had a Myocardial Infarction

Assess cardiovascular function, including:

- Current vital signs (compare with previous to identify changes)
- Recurrence of discomfort (characteristics, frequency, onset)
- Indications of heart failure (weight gain, crackles, cough, dyspnea)
- Adequacy of tissue perfusion (mentation, skin temperature, peripheral pulses, urine output)
- Indications of serious dysrhythmia (very irregular pulse, palpitations with fainting or near fainting)

Assess coping skills, including:

- Is patient displaying denial, anger, or fear?
- Is the caregiver providing adequate support?
- Are the patient and caregiver disagreeing about treatment?

Assess functional ability, including:

- Activity tolerance (examine the patient's activity diary: review distance, duration, frequency, and symptoms occurring during exercise)
- Activities of daily living (is any assistance needed?)
- Household chores (who performs them?)
- Does patient plan to return to work? When?

Assess nutritional status, including:

- Food intake (review patient's intake of fats and cholesterol)

Assess patient's understanding of illness and treatment, including:

- How to treat chest discomfort
- Signs and symptoms to report to health care provider
- Dosage, effects, and side effects of medications
- How to advance and when to limit activity
- Modification of risk factors for coronary artery disease

CHART 40-8 NURSING FOCUS ON THE OLDER ADULT

Coronary Artery Bypass Graft Surgery

- Be aware that perioperative mortality rates are higher for the older patient than for the patient younger than 60 years.
- Monitor neurologic and mental status carefully because older adults are more likely to have transient neurologic deficits after coronary artery bypass graft (CABG) surgery than younger adults are.
- Observe for side effects of cardiac drugs because older patients are more likely to develop toxic effects from positive inotropes (dobutamine) and potent antihypertensives (nitroglycerin or nitroprusside).
- Monitor the patient closely for dysrhythmias because older adults are more likely to have dysrhythmias, such as atrial fibrillation or supraventricular tachycardia, after CABG surgery.
- Be aware that recuperation after CABG surgery is slower for older patients and that their average hospital stay is longer.
- Teach the patient and family that during the first 2 to 5 weeks after discharge, fatigue, chest discomfort, and lack of appetite may be particularly bothersome for older adults.
- Teach patient to let someone know where he or she is walking outside.

Cardiac rehabilitation is available in most communities for patients after an MI or CABG surgery, but only a small percentage participate in structured rehabilitation programs. Dolansky et al. (2010) found that although post-acute care (PAC) is available for older adults, only 50% of patients who had a myocardial infarction (MI) received PAC. Only 44% of patients who had cardiac surgery participated in post-acute care (see the Evidence-Based Practice box below).

The most frequently cited reasons for nonparticipation are lack of insurance coverage, a physician's decision that it is unnecessary, and the patient's decision that it is not necessary. Those who participate in these programs report greater improvement in exercise tolerance and improved ability to control stress. However, no difference in their return to work has been seen (AHA, 2010).

Teaching for Self-Management

The need for health teaching depends in part on the treatment plan or type of procedure that the patient received. Because hospital stays are short and patients are quite ill during hospitalization, most in-hospital education programs concentrate on the skills essential for self-care after discharge.

As part of home visits or a cardiac rehabilitation program, identify the additional educational needs of the patient and

family and their readiness to learn. Develop a teaching plan, which usually includes education about the normal anatomy and physiology of the heart, the pathophysiology of angina and MI, risk factor modification, activity and exercise protocols, cardiac drugs, and when to seek medical assistance. Teach patients that myocardial healing after an MI begins early and is usually complete in 6 to 8 weeks. Remind those who have undergone traditional CABG that the sternotomy should heal in about 6 to 8 weeks but upper body exercise needs to be limited for several months.

Patients who have undergone CABG require instruction on incision care for the sternum and the graft site. Teach them to inspect the incisions daily for any redness, swelling, or drainage. The leg of a saphenous vein donor site is often edematous. Instruct patients to avoid crossing legs, to wear elastic stockings until the edema subsides, and to elevate the surgical limb when sitting in a chair. Teach patients who have had a radial artery graft to open and close the hand vigorously 10 times every 2 hours.

Risk Factor Modification. Modification of risk factors is a necessary part of a patient's management and involves changing his or her health maintenance patterns. Such modifications may include tobacco cessation, altered nutritional habits, regular exercise, BP control, and blood glucose control. Each of these factors has been discussed earlier in this chapter in the Health Promotion and Maintenance section.

For patients who use tobacco, explain its negative effects, especially cigarette smoking. Many patients choose to quit smoking soon after an MI. Chapter 38 also provides information on this lifestyle change.

The mainstays of cholesterol control are nutritional therapy and anti-hyperlipidemic agents, as described in Chapter 38. Teach patients to avoid adding salt when beginning a meal. A reduction of 80 mg/day of sodium can reduce the systolic blood pressure (SBP) by 5 mm Hg and 3 mm Hg for the diastolic blood pressure (DBP). Maintain adequate dietary potassium, calcium, and magnesium intake. Increasing potassium may reduce the SBP by 8 mm Hg. Booklets and cookbooks that can assist the patient in learning to cook with reduced fats, oils, and salt are available from the American Heart Association (AHA).

Collaborate with the physical therapist to establish an activity and exercise schedule as part of rehabilitation, depending on the cardiac procedure that was performed. Instruct the patient to remain near home during the first week after discharge and to continue a walking program. Patients may engage in light housework or any activity done while sitting and that does not precipitate angina. During the second week, they are encouraged to increase social activities and possibly to return to work part-time. By the third week, they may begin to lift objects as heavy as 15 pounds (e.g., 2 gallons of milk) but should avoid lifting or pulling heavier objects for the first 6 to 8 weeks. Chart 40-9 lists suggested instructions for activity level.

Patients may begin a simple walking program by walking 400 feet twice a day at the rate of 1 mile/hr the first week after discharge and increasing the distance and rate as tolerated, usually weekly, until they can walk 2 miles at 3 to 4 miles/hr. Teach them to take their pulse reading before, halfway through, and after exercise. Teach the patient to stop exercising if the target pulse rate is exceeded or if dyspnea or angina develops.

EVIDENCE-BASED PRACTICE

How Many Older Adults Who Had a Cardiac Event Participate in Post-Acute Care Programs?

Dolansky, M.A., Xu, F., Zullio, M., Shishehbor, B., Moore, S.M., & Rimm, A.A. (2010). Post-acute care services received by older adults following a cardiac event: A population-based analysis. *Journal of Cardiovascular Nursing*, 25(4), 342-349.

Post-acute care (cardiac rehabilitation) is widely available in a number of settings, including home care, nursing homes, and transitional care units. A cross-section research design was used to review the 2003 Medicare database of all older adults who had cardiac events, such as valve surgery, myocardial infarction (MI), coronary artery bypass graft (CABG), and percutaneous transluminal coronary angioplasty (PTCA), to determine what percentage of patients in each category received post-acute care (PAC). Medical patients used more skilled nursing home care, and surgical patients participated more in home care. Only 65% who had valve surgery, 50% who had an MI, 44% who had a CABG, and 5% who had PTCA participated in cardiac rehabilitation programs after hospitalization. Asians, Hispanics, and Native Americans were less likely to use these programs. The cause is not known.

Level of Evidence: 1

This study was an analysis of a large population sample (over 1 million Medicare patients in the database) so that conclusions could be drawn for generalization.

Commentary: Implications for Nursing Research and Practice

In view of the low percentages of older adults who received post-acute care (PAC) after a cardiac event, nurses need to encourage all patients to participate in cardiac rehabilitation. Collaborate with the case manager or discharge planner to ensure a smooth transition and appropriate placement. Further studies need to be conducted to explain why the identified minority groups use PAC less often than their Euro-American counterparts.

CHART 40-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Activity for the Patient with Coronary Artery Disease

- Begin by walking the same distance at home as in the hospital (usually 400 feet) three times each day.
- Carry nitroglycerin with you.
- Check your pulse before, during, and after the exercise.
- Stop the activity for a pulse increase of more than 20 beats/min, shortness of breath, angina, or dizziness.
- Exercise outdoors when the weather is good.
- Gradually increase the walking until the distance is $\frac{1}{4}$ mile twice daily (usually the end of the second week).
- After an exercise tolerance test and with your physician's approval, walk at least three times each week, increasing the distance by $\frac{1}{2}$ mile every other week, until the total distance is 2 miles.
- Avoid straining (lifting, push-ups, pull-ups, and straining at bowel movements).

After a limited exercise tolerance test, the physical therapist or nurse encourages the patient to join a formal exercise program, ideally one that assists him or her in monitoring cardiovascular progress. The program should include 5- to 7-minute warm-up and cool-down periods, as well as 30 minutes of aerobic exercise. The patient should engage in aerobic exercise a minimum of three (and preferably five) times a week.

Complementary and Alternative Therapies. Additional therapies can aid in reducing the patient's anxiety about progressive activity both in the immediate postoperative period and during the rehabilitation phase. Many patients who have had cardiac surgery or other invasive procedures use complementary and alternative therapies. However, they often do not share with their health care providers that they use these therapies. Techniques such as progressive muscle relaxation, guided imagery, music therapy, pet therapy, and therapeutic touch may decrease anxiety, reduce depression, and increase compliance with activity and exercise regimens after heart surgery.

Sexual Activity. Sexual activity is often a subject of great concern to patients and their partners. Inform the patient and his or her partner that engaging in their usual sexual activity is unlikely to damage the heart. Patients can resume sexual intercourse on the advice of the health care provider, usually after an exercise tolerance assessment. In general, those who can walk one block or climb two flights of stairs without symptoms can usually safely resume sexual activity.

Suggest that initially these patients have intercourse after a period of rest. They might try having intercourse in the morning when they are well rested or wait $1\frac{1}{2}$ hours after exercise or a heavy meal. The position selected should be comfortable for both the patient and his or her partner so that no undue stress is placed on the heart or suture line.

Drug Therapy. Assess patients with diabetes mellitus for their ability to control hyperglycemia. Review the prescribed dosage of insulin or oral antidiabetic drugs with the patient and family. The patient and/or family should demonstrate accurate testing of blood for glucose levels and the technique for insulin administration, if used.

CHART 40-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Management of Chest Pain at Home

- Keep fresh nitroglycerin available for immediate use.
- At the first indication of chest discomfort, cease activity and sit or lie down.
- Place one nitroglycerin tablet or spray under your tongue, allowing the tablet to dissolve.
- Wait 5 minutes for relief.
- If no relief results, call 911 for transportation to a health care facility.
- While waiting for emergency medical services (EMS), repeat the nitroglycerin and wait 5 more minutes.
- If there is no relief, repeat and wait 5 more minutes.
- Carry a medical identification card or wear a bracelet or necklace that identifies a history of heart problems.

Teach the patient about the type of prescribed cardiac drugs, the benefit of each drug, potential side effects, and the correct dosage and time of day to take each drug. Drug regimens vary considerably. However, many patients with angina are discharged while taking aspirin, a beta blocker, a calcium channel blocker, an anti-hyperlipidemic agent, and a nitrate. Those who have experienced an MI may require aspirin, a beta blocker, an anti-hyperlipidemic agent, and an ACE inhibitor and/or an ARB. The regimen can be complex. Determine whether the patient can comply with the instructions.

NURSING SAFETY PRIORITY

Drug Alert

Use of sublingual or spray nitroglycerin (NTG) deserves special attention. *Teach the patient to carry NTG at all times.* Keep the tablets in a glass, light-resistant container. The drug should be replaced every 3 to 5 months before it loses its potency or stops producing a tingling sensation when placed under the tongue. [Chart 40-10](#) gives instructions for management of chest discomfort at home.

Seeking Medical Assistance. Teach patients to notify their health care provider if they have:

- Heart rate remaining less than 50 after arising
- Wheezing or difficulty breathing
- Weight gain of 3 pounds in 1 week or 1 to 2 pounds overnight
- Persistent increase in NTG use
- Dizziness, faintness, or shortness of breath with activity

Remind them to always call 911 for transportation to the hospital if they have:

- Chest discomfort that does not improve after 5 minutes or 1 sublingual NTG tablet or spray
- Extremely severe chest or epigastric discomfort with weakness, nausea, or fainting
- Other associated symptoms that are particular to them, such as fatigue and nausea

Health Care Resources

The American Heart Association (AHA) is an excellent source for booklets, films, CDs, DVDs, cookbooks, and professional service referrals for the patient with coronary artery disease (CAD). Many local chapters have their own cardiac rehabilitation programs.

Within the community, cardiac rehabilitation programs may be affiliated with local hospitals, community centers, or other facilities, such as clinics. Many shopping malls open before shopping hours to allow a measured walking program indoors. This opportunity is particularly popular with older patients because it provides a good support group and allows for an appropriate place to exercise in inclement weather.

Mended Hearts is a nationwide program with local chapters that provides education and support to coronary artery bypass graft (CABG) patients and their families. Smoking-cessation programs and clinics and weight-reduction programs are located within the community. Many hospitals also sponsor health fairs, BP screening, and risk factor modification programs.

EVALUATION: OUTCOMES

Evaluate the care of the patient with CAD based on the identified priority patient problems. The expected outcomes are that the patient will:

- State that discomfort or other symptoms are alleviated
- Have adequate blood flow through the coronary vasculature to ensure heart function

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation and tissue perfusion as a result of coronary artery disease?

- Report of pain (chest, shoulder, arm, jaw, back, or abdomen)
- Report of persistent indigestion
- Dyspnea
- Diaphoresis
- Report of nausea
- Vomiting
- Anxious behavior
- Report of palpitations
- Report of fatigue
- Disorientation or acute confusion (especially in older adults)

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate oxygenation and tissue perfusion as a result of coronary artery disease?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Taking 12-lead ECG
- Assessing level of consciousness and cognition
- Conducting complete pain assessment

DECISION-MAKING CHALLENGE

Teamwork and Collaboration; Safety

A 69-year-old woman had two myocardial infarctions within the same month. She had a percutaneous transluminal coronary angioplasty and three stents placed and is now pain-free. The patient is admitted to the transitional care unit (TCU) for cardiac rehabilitation for 20 days. Her daughter works as a clerk in a retail store and is unable to care for her mother after the patient leaves the TCU. There are no other family members who could care for her. The patient lives alone on her monthly Social Security check and has no other source of income or financial assets.

1. What are the expected outcomes for this patient as a result of cardiac rehabilitation?
2. What is the role of the physical therapist in cardiac rehabilitation?
3. What other members of the health care team will the nurse collaborate with to ensure the patient's continuity of care?
4. Because there are no family members to care for this patient after discharge, what options does she have?

- Walk 200 feet four times a day without discomfort, shortness of breath, or other symptoms of CAD
- Identify support systems and other sources to assist in effective coping with the cardiac event
- Be free of complications, such as dysrhythmias and heart failure

- Drawing blood for laboratory assessment (e.g., troponins)
- Auscultating breath sounds for crackles or wheezes (left-sided heart failure)
- Auscultating heart for abnormal heart sounds
- Assessing for peripheral edema (right-sided heart failure)

Respond by:

- Calling 911 if patient is not in hospital setting OR notifying physician or Rapid Response Team in hospital setting
- Ensuring that patient rests
- Giving oxygen
- Giving nitroglycerin tablet
- Maintaining or starting IV line
- Administering morphine sulfate if MI suspected or diagnosed

On what should you REFLECT?

- Observe patient for decreased report of pain and associated symptoms.
- Continue to monitor oxygen.
- Continue to monitor for dysrhythmias and vital signs.
- Think about what could have precipitated this coronary event.
- Think about how you responded.
- Develop teaching plan for the patient to help prevent further episodes.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with members of the interdisciplinary health care team members (e.g., physical therapist, case manager, home care providers) when caring for the cardiac patient.
- Ensure effective communication among all health care providers, especially when transferring the patient from the hospital to community-based settings.

Health Promotion and Maintenance

- Assist patients in securing personal medical identification alert devices that provide information regarding their heart conditions.
- In collaboration with the interdisciplinary health care team, assess the patient for activity tolerance and help design an appropriate exercise regimen.
- Teach the patient about the signs and symptoms of cardiovascular disease and when to seek medical assistance.
- Assess the patient for risk factors for coronary artery disease (CAD), such as obesity, smoking, positive family history, cholesterol management, and the diagnosis and treatment of hypertension.
- Teach patients about the importance of decreasing their risk for CAD.
- Be sure that older adults have adequate support at home after discharge from the hospital. Refer patients and families to appropriate community programs and support groups.

Psychosocial Integrity

- Allow patients to verbalize and express feelings of fear, anxiety, anger, denial, and grief regarding their CAD.

- Address the needs of the family and significant others, and provide teaching and information regarding the disease process. Clarify any misconceptions.

Physiological Integrity

- Explain to patients the need to make lifestyle changes for modifiable risk factors. Nonmodifiable risk factors like age and family history cannot be changed (see [Chart 40-1](#)).
- Teach patients that angina is the pain associated with decreased blood flow to the heart muscle. An MI indicates necrosis of heart muscle tissue (see [Chart 40-2](#)).
- Identify and interpret diagnostic values for cardiac markers, such as troponins and myoglobin, and other indicators of CAD.
- Monitor patients receiving thrombolytics and anticoagulants, such as heparin, for bleeding.
- For patients undergoing invasive cardiac procedures, assess for signs and symptoms of active bleeding.
- Interpret and assess the patient with CAD for dysrhythmias.
- Evaluate the patient for pain characteristics (e.g., type, location, duration, cause, intensity, and measures taken to relieve symptoms).
- Teach patients and their families about drug therapy, including how to use nitroglycerin if they have chest or other cardiac-related pain (see [Chart 40-4](#)).
- Identify and assess for complications for post-cardiac surgery patients, especially fluid and electrolyte imbalance, bleeding, hypothermia, hypertension, and angina pain.
- Provide emergency care for the patient with chest pain as described in [Chart 40-3](#).

Problems of Tissue Perfusion

Management of Patients with Problems of the Hematologic System

CHAPTER 41

Assessment of the Hematologic System

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Verify that the patient has given informed consent for a bone marrow aspiration or biopsy.

Health Promotion and Maintenance

2. Assess the patient's endurance in performing ADLs.
3. Perform a clinical health history and risk assessment for hematologic function.

Psychosocial Integrity

4. Teach patients and family members about what to expect during procedures to assess hematologic function.

Physiological Integrity

5. Explain the relationship between hematologic problems and the need for oxygen.
6. Describe the hematologic changes associated with aging.
7. Describe the role of platelets in hemostasis.
8. Interpret blood cell counts and clotting tests to assess hematologic status.
9. Explain the effects of anticoagulants, fibrinolytics, and inhibitors of platelet activity on hematologic function.
10. Prioritize nursing care for the patient after bone marrow aspiration.

The blood, blood cells, lymph, and organs involved with blood formation or blood storage together compose the hematologic system. This system is important for *oxygenation* and tissue perfusion because the blood itself is one of the oxygen delivery systems (Fig. 41-1). All systems depend on

the blood for oxygen perfusion. Thus any problem of the hematologic system affects total body health and well-being. This chapter, together with Chapter 19, reviews the normal physiology of the hematologic system and assessment of hematologic status.

ANATOMY AND PHYSIOLOGY REVIEW

Bone Marrow

Bone marrow is the tissue responsible for blood formation. It produces red blood cells (RBCs, erythrocytes), white blood cells (WBCs, leukocytes), and platelets. Bone marrow also is involved in the immune responses (see Chapter 19).

Each day the bone marrow normally releases about 2.5 billion RBCs, 2.5 billion platelets, and 1 billion WBCs per kilogram of body weight. In adults, cell-producing marrow is present only in flat bones (sternum, skull, pelvic and shoulder girdles) and the ends of long bones. With aging, fatty tissue slowly replaces active bone marrow and only a small portion of the remaining marrow continues to produce blood in older adults (Touhy & Jett, 2010).

The bone marrow first produces **blood stem cells**, which are immature, unspecialized (undifferentiated) cells. These

are capable of becoming any one of several types of blood cells: RBCs, WBCs, or platelets, depending on the body's needs (Fig. 41-2) (McCance et al., 2010).

The next stage in blood cell production is the *committed stem cell* (also called the *precursor cell*). A committed stem cell enters one growth pathway and can at that point specialize (differentiate) into only one cell type. Committed stem cells actively divide but require the presence of a specific growth factor for specialization. For example, erythropoietin is a growth factor made in the kidneys that is specific for the RBC. Other growth factors influence WBC and platelet growth (see Chapters 19, 24, and 42 for discussion of growth factors and cytokines).

Blood Components

Blood is composed of plasma and cells. Plasma is part of the body's extracellular fluid. It is similar to the interstitial fluid found between tissue cells, but plasma contains much more protein. The three major types of plasma proteins are albumin, globulins, and fibrinogen.

Albumin maintains the osmotic pressure of the blood, preventing the plasma from leaking into the tissues (see Chapter 13). *Globulins* have many functions, such as transporting other substances and, as antibodies, protecting the body against infection. *Fibrinogen* is an inactive protein that is activated to form fibrin. Fibrin molecules assemble together to form structures important in the blood clotting process.

The blood cells include RBCs, WBCs, and platelets. These cells differ in structure, site of maturation, and function.

Red blood cells (erythrocytes) are the largest proportion of blood cells. Mature RBCs have no nucleus and have a biconcave disk shape. Together with a flexible membrane, this feature allows RBCs to change their shape without breaking as they pass through narrow, winding capillaries. The number of RBCs a person has varies with gender, age, and

FIG. 41-1 Role of the hematologic system in oxygenation and tissue perfusion. RBCs, Red blood cells.

FIG. 41-2 Bone marrow cell growth and blood cell differentiation pathways.

general health, but the normal range is from 4,200,000 to 6,100,000/mm³.

As shown in Figs. 41-2 and 41-3, RBCs start out as stem cells, enter the myeloid pathway, and progress in stages to mature RBCs (erythrocytes). Healthy, mature RBCs have a life span of about 120 days after being released into the blood. As RBCs age, their membranes become more fragile. These old cells are trapped and destroyed in the tissues, spleen, and liver. Some parts of destroyed RBCs (e.g., iron, hemoglobin) are recycled and used to make new RBCs.

The RBCs produce hemoglobin (Hgb). Each normal mature RBC contains hundreds of thousands of hemoglobin molecules. The heme part of each hemoglobin molecule needs a molecule of iron to be able to transport up to four molecules of oxygen. *Therefore iron is an essential part of hemoglobin.* The globin portion of hemoglobin carries carbon dioxide. RBCs also are buffers and help maintain acid-base balance.

The most important feature of hemoglobin is its ability to combine loosely with oxygen. With only a small drop in tissue oxygen levels, an increase in the transfer of oxygen from hemoglobin to tissues occurs, known as **oxygen dissociation**. See Chapter 29 for a complete discussion of the physiological concept of oxygen dissociation.

The total number of RBCs a person has is carefully controlled to ensure that enough are present for good oxygenation without having too many cells that could “thicken” the blood and slow its flow. Thus RBC production or **erythropoiesis** (selective growth of stem cells into mature erythrocytes) must be properly balanced with RBC destruction or loss. When balanced, this process helps tissue perfusion by

ensuring adequate delivery of oxygen. The trigger for RBC production is an increase in the need for tissue oxygenation. The kidney produces the RBC growth factor *erythropoietin* at the same rate as RBC destruction or loss occurs to maintain a constant normal level of circulating RBCs. When tissue oxygenation is less than normal (**hypoxia**), the kidney releases more erythropoietin. This growth factor then stimulates increased RBC production in the bone marrow. When tissue oxygenation is normal or high, the kidney reduces erythropoietin levels, slowing the production of RBCs. Synthetic erythropoietin (Procrit, Epogen, EPO) has the same effect on bone marrow as the naturally occurring erythropoietin.

Many substances are needed to form hemoglobin and RBCs, including iron, vitamin B₁₂, folic acid, copper, pyridoxine, cobalt, and nickel. A lack of any of these substances can lead to anemia. Anemia is the result of any problem that reduces the function or the number of RBCs to the point that tissue oxygen needs are not completely met.

White blood cells (WBCs, leukocytes) perform actions important for protection through inflammation and immunity (Table 41-1). The many types of WBCs all have specialized functions. Many WBCs are formed in the bone marrow and are part of the hematologic system. WBC function is presented in Chapter 19.

Platelets are the third type of blood cells. They are the smallest of the blood cells, formed as fragments of a giant

FIG. 41-3 Erythrocyte (red blood cell) growth pathway.

TABLE 41-1 FUNCTIONS OF SPECIFIC LEUKOCYTES

LEUKOCYTE	FUNCTION
Inflammation	
Neutrophil	Nonspecific ingestion and phagocytosis of microorganisms and foreign protein
Macrophage	Nonspecific recognition of foreign proteins and microorganisms; ingestion and phagocytosis
Monocyte	Destruction of bacteria and cellular debris; matures into macrophage
Eosinophil	Weak phagocytic action; releases vasoactive amines during allergic reactions
Basophil	Releases histamine and heparin in areas of tissue damage
Antibody-Mediated Immunity	
B-lymphocyte	Becomes sensitized to foreign cells and proteins
Plasma cell	Secretes immunoglobulins in response to the presence of a specific antigen
Memory cell	Remains sensitized to a specific antigen and can secrete increased amounts of immunoglobulins specific to the antigen
Cell-Mediated Immunity	
T-lymphocyte helper/inducer T-cell	Enhances immune activity through the secretion of various factors, cytokines, and lymphokines
Cytotoxic-cytolytic T-cell	Selectively attacks and destroys non-self cells, including virally infected cells, grafts, and transplanted organs
Natural killer cell	Nonselectively attacks non-self cells, especially body cells that have undergone mutation and become malignant; also attacks grafts and transplanted organs

precursor cell in the bone marrow, the megakaryocyte. Platelets stick to injured blood vessel walls and form platelet plugs that can stop the flow of blood from the injured site. They also produce substances important to blood clotting (*coagulation*), and perform most of their functions by *aggregation* (clumping together). Platelets help keep blood vessels intact by initiating repair after damage to small blood vessels.

Bone marrow production of platelets also is precisely controlled by the growth factor *thrombopoietin*. After platelets leave the bone marrow, they are stored in the spleen and then released slowly to meet the body's needs. Normally, 80% of platelets circulate and 20% are stored in the spleen. Each platelet has a life span of 1 to 2 weeks.

Accessory Organs of Blood Formation

The spleen and liver are important accessory organs for blood production. They help regulate the growth of blood cells and form factors that ensure proper blood clotting.

The spleen is located under the diaphragm to the left of the stomach. It contains three types of tissue: white pulp, red pulp, and marginal pulp. These tissues all help balance blood cell production with blood cell destruction and assist with immunity. White pulp is filled with white blood cells (WBCs), especially lymphocytes and macrophages. It is a major site of antibody production. As whole blood filters through the white pulp, bacteria and old RBCs are removed. Red pulp contains enlarged blood vessels (sinuses) that store RBCs and platelets. Marginal pulp contains the ends of many arteries and other blood vessels.

The spleen destroys old or imperfect RBCs, breaks down the hemoglobin released from these destroyed cells, stores platelets, and filters antigens. Anyone who has had a splenectomy has reduced immune functions and is less able to remove disease-causing organisms, increasing the risk for infection and sepsis.

The liver produces prothrombin and most of the blood clotting factors. In addition, proper liver function and bile production are important in forming vitamin K in the intestinal tract. (Vitamin K is needed to produce blood clotting factors VII, IX, and X and prothrombin.) Large quantities of whole blood and blood cells can be stored in the liver. The liver also stores extra iron within the protein *ferritin*.

Hemostasis/Blood Clotting

Hemostasis is the multi-step process of controlled blood clotting. With proper hemostasis, localized blood clotting occurs in damaged blood vessels to prevent excessive blood loss while blood continues to circulate to all other areas. This important function is a complex process that balances blood clotting actions with anti-clotting actions. When injury occurs, hemostasis begins with the formation of a platelet plug and continues with a series of events that eventually cause the formation of a fibrin clot. Three sequential processes result in blood clotting: platelet aggregation with formation of a platelet plug, the blood clotting cascade, and the formation of a complete fibrin clot.

Platelet aggregation begins forming a platelet plug by having platelets clump together, a process essential for blood clotting. Platelets normally circulate as individual cell-like structures. They are not attracted to each other and do not clump together until activated. Activation causes platelet membranes to become sticky, allowing them to clump together. When platelets clump, they form large, semisolid

plugs in blood vessel lumens and walls, disrupting local blood flow. *These platelet plugs are not clots and last only a few hours. Thus they cannot provide complete hemostasis.*

Substances that cause platelets to clump include adenosine diphosphate (ADP), calcium, thromboxane A₂, and collagen. Platelets themselves secrete some of these substances, and other activating substances are external to the platelet. Platelet plugs start the cascade reaction that ends with local blood clotting and also are important at most steps within the cascade. When too few platelets are present, blood clotting is impaired, increasing the person's risk for bleeding and hemorrhage.

Blood clotting is a cascade triggered by the formation of a platelet plug. The beginning of the blood clotting cascade is then rapidly amplified. The final result is much larger than the triggering event. In this sense, the cascade works like a landslide. A few small pebbles rolling down a steep hillside can dislodge large rocks and pieces of soil, causing a final enormous movement of earth. Just like landslides, cascade reactions are hard to stop once set into motion.

Intrinsic factors are conditions directly in the blood itself that first activate platelets and then trigger the blood clotting cascade (Fig. 41-4). These conditions include circulating debris and prolonged venous stasis. Continuing the cascade to the point of blood clotting requires having sufficient amounts of all the different clotting factors and cofactors (Table 41-2).

Extrinsic factors are outside of the blood that can also activate platelets. The most common extrinsic event is trauma that damages blood vessels and exposes the platelets to collagen. Collagen then activates platelets to form a platelet plug within seconds of the trauma. The blood clotting cascade is started sooner by the extrinsic pathway because some of the steps of the intrinsic pathway are bypassed. Other blood vessel changes that can activate platelets include inflammation, bacterial toxins, or foreign proteins.

Whether the platelet plugs are formed because of abnormal blood (intrinsic factors) or by exposure to inflamed or damaged blood vessels (extrinsic factors), the end result of the cascade is the same: *formation of a fibrin clot and local blood coagulation.*

The steps of the cascade between the formation of a platelet plug and the formation of a fibrin clot depend on the presence of specific clotting factors. In addition, calcium and more platelets are needed at every step.

Clotting factors (see Table 41-2) are inactive enzymes that become activated in a sequence. The last part of the sequence is the activation of fibrinogen into fibrin. At each step, the activated enzyme from the previous step activates the next enzyme. The last two steps in the cascade are the activation of thrombin from prothrombin and the conversion (by thrombin) of fibrinogen into fibrin. Only fibrin molecules can begin the formation of a true clot.

Fibrin clot formation is the last phase of blood clotting. Fibrinogen is an inactive protein made in the liver. The enzyme *thrombin* removes the end portions of fibrinogen, converting it to active fibrin. Active fibrin molecules then link together to form fibrin threads. Fibrin threads make a netlike base to form a blood clot.

After the fibrin mesh is formed, clotting factor XIII tightens up the mesh, making it more dense and stable. More platelets stick to the threads of the mesh and attract other blood cells and proteins to form an actual blood clot. As this

FIG. 41-4 Summary of the blood clotting cascade.

clot tightens (retracts), the serum is squeezed out and clot formation is complete.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

How does aspirin interfere with blood clotting?

- A. Prevents vitamin K synthesis
- B. Inhibits the activation of platelets
- C. Increases the rate of platelet destruction
- D. Prevents fibrin molecules from assembling into long strands

Anti-Clotting Forces

Because blood clotting occurs through a rapid cascade process, in theory it keeps forming fibrin clots whenever the cascade is set into motion until all blood throughout the entire body has coagulated. Such widespread clotting would

lead to death. Therefore, whenever the blood clotting cascade is started, anti-clotting forces are also started to limit clot formation only to damaged areas so that normal blood flow is maintained everywhere else. When blood clotting and anti-clotting actions are normal and balanced, clotting occurs only where it is needed and normal blood flow elsewhere is maintained. The anti-clotting forces involve two types of actions. One action ensures that activated clotting factors are present only in limited amounts. The other action, **fibrinolysis**, prevents over-enlargement of the fibrin clot.

When the blood clotting cascade is activated, certain anti-clotting substances are also activated. Known anti-clotting proteins include protein C, protein S, and antithrombin III. Protein C and protein S increase the breakdown of clotting factors V and VIII. Antithrombin III inactivates thrombin and clotting factors IX and X. These actions prevent clots from becoming too large or forming in an area where clotting

TABLE 41-2 THE CLOTTING FACTORS

FACTOR	ACTION	FACTOR	ACTION
I: Fibrinogen	Factor I is converted to fibrin by the enzyme <i>thrombin</i> . Individual fibrin molecules form fibrin threads, which are the scaffold for clot formation and wound healing.	VIII: Antihemophilic factor	Factor VIII together with activated factor IX enzymatically activates factor X. In addition, factor VIII combines with another protein (von Willebrand's factor) to help platelets adhere to capillary walls in areas of tissue injury. A lack of factor VIII is the basis for classic hemophilia (hemophilia A).
II: Prothrombin	Factor II is the inactive precursor of thrombin. Prothrombin is activated to thrombin by coagulation factor X (Stuart-Prower factor). After it is activated, thrombin converts fibrinogen (coagulation factor I) into fibrin and activates factors V and VIII. Synthesis is vitamin K-dependent.	IX: Plasma thromboplastin component (Christmas factor)	Factor IX, when activated, activates factor X to convert prothrombin to thrombin. This factor is essential in the common pathway between the intrinsic and extrinsic clotting cascades. A lack of factor IX causes hemophilia B. Synthesis is vitamin K-dependent.
III: Tissue thromboplastin	Factor III interacts with factor VII to initiate the extrinsic clotting cascade.	X: Stuart-Prower factor	Factor X, when activated, converts prothrombin into thrombin. Synthesis is vitamin K-dependent.
IV: Calcium	Calcium (Ca^{2+}), a divalent cation, is a cofactor for most of the enzyme-activated processes required in blood coagulation. Calcium also enhances platelet aggregation and makes red blood cells clump together.	XI: Plasma thromboplastin antecedent	Factor XI, when activated, assists in the activation of factor IX. However, a similar factor must exist in tissues. People who are deficient in factor XI have mild bleeding problems after surgery but do not bleed excessively as a result of trauma.
V: Proaccelerin	Factor V is a cofactor for activated factor X, which is essential for converting prothrombin to thrombin.	XII: Hageman factor	Factor XII is critically important in the intrinsic pathway for the activation of factor XI.
VI: Discovered to be an artifact	No factor VI is involved in blood coagulation.	XIII: Fibrin-stabilizing factor	Factor XIII assists in forming cross-links among the fibrin threads to form a strong fibrin clot.
VII: Proconvertin	Factor VII activates factors IX and X, which are essential in converting prothrombin to thrombin. Synthesis is vitamin K-dependent.		

FIG. 41-5 The process of fibrinolysis.

is not needed. Deficiency of any of these anti-clotting factors increases the risk for pulmonary embolism, myocardial infarction, and strokes.

Fibrinolysis limits the size of blood clots by dissolving fibrin clot edges with special enzymes (Fig. 41-5). The process starts by activating plasminogen to plasmin. Plasmin, an enzyme, then digests fibrin, fibrinogen, and prothrombin, controlling the size of the fibrin clot.

Hematologic Changes Associated with Aging

Aging changes the cellular and plasma components of blood (Touhy & Jett, 2010). Chart 41-1 lists assessment tips for older adults. The older adult has a decreased blood volume with lower levels of plasma proteins. The lower plasma

protein level may be related to a low dietary intake of proteins, as well as to reduced protein production by the older liver.

As bone marrow ages, it produces fewer blood cells. Total red blood cell (RBC) and white blood cell (WBC) counts (especially lymphocyte counts) are lower among older adults. Platelet counts do not change with age. Lymphocytes become less reactive to antigens and lose immune function. Antibody levels and responses are lower and slower in older adults. The WBC count does not rise as high in response to infection in older people as it does in younger people.

Hemoglobin levels also change with age. Hemoglobin levels in men and women fall after middle age. Iron-deficient diets may play a role in this reduction.

CHART 41-1 NURSING FOCUS ON THE OLDER ADULT

Hematologic Assessment

FINDINGS IN HEMATOLOGIC DISORDERS	NORMAL CHANGES IN THE OLDER ADULT	SIGNIFICANCE/ALTERNATIVES
Nail Beds (for Capillary Refill) Pallor or cyanosis may indicate a hematologic disorder.	Thickened or discolored nails make viewing skin color beneath the nails impossible.	Use another body area, such as the lip, to assess central capillary refill.
Hair Distribution Thin or absent hair on the trunk or extremities may indicate poor circulation to a particular area.	Progressive loss of body hair is a normal facet of aging.	A relatively even pattern of hair loss that has occurred over an extended period is not significant.
Skin Moisture Skin dryness may indicate any of a number of hematologic disorders.	Skin dryness is a normal result of aging.	Skin moisture is not usually a reliable indicator of an underlying pathologic condition in the older adult.
Skin Color Skin color changes, especially pallor and jaundice, are associated with some hematologic disorders.	Pigment loss and skin yellowing are common changes associated with aging.	Pallor in an older adult may not be a reliable indicator of anemia. Laboratory testing is required. Yellow-tinged skin in an older adult may not be a reliable indicator of increased serum bilirubin levels. Laboratory testing is required.

CHART 41-2 HEMATOLOGIC ASSESSMENT

Using Gordon's Functional Health Patterns**Activity-Exercise Pattern**

- How does your energy level seem to you compared with last year at this time?
- Do you feel rested after a typical night's sleep?
- Have you experienced any dizziness or light-headedness?
- Does your heart ever seem to pound?
- How much exercise do you get? How often? What type?
- Do you feel you have enough energy to do what you want or need to do?

Nutrition-Metabolic Pattern

- Have you noticed any change in your skin lately?
- How easily do you bruise?
- Do your gums ever bleed? Under what conditions?
- How much meat do you eat in a week?
- How often do you eat salads or other green leafy vegetables?
- Are you taking any vitamin or mineral supplements?
- Do your feet and hands usually feel warm or cold?
- Has your weight changed by 5 pounds or more this year?
- How often do you take aspirin or any other NSAID?
- What drugs do you take daily?

Modified from Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

ASSESSMENT METHODS**Patient History**

Chart 41-2 lists questions based on Gordon's Functional Health Patterns to ask during assessment of hematologic function. Age and gender are important to consider when assessing the patient's hematologic status. Bone marrow function and immune activity decrease with age.

Liver function, the presence of known immunologic or hematologic disorders, current drug use, dietary patterns,

WOMEN'S HEALTH CONSIDERATIONS

At all ages, women have lower blood cell counts than do men. This difference is greater during menstrual years because blood loss from menstruation may occur slightly faster than blood cell production. This gender difference also may be related to a blood dilution caused by fluid retention from female hormones.

and socioeconomic status are important to hematologic assessment. Because the liver makes clotting factors, ask about manifestations that may indicate liver problems, such as jaundice, anemia, and gallstones. Previous radiation therapy for cancer may impair hematologic function if marrow-forming bones were in the radiation path.

Ask about the patient's occupation, hobbies, and the location of housing. This information may identify exposure to agents that affect bone marrow and hematologic function.

Check all drugs the patient has used in the past 3 weeks, especially antibiotics, because these drugs can lead to clotting problems or bone marrow depression. Table 41-3 lists drugs known to change hematologic function.

Ask the patient about use of blood "thinners" and NSAIDs, which change blood clotting activity. Such drugs include anti-coagulants, fibrinolytics, and platelet inhibitors. These drugs are referred to as "blood thinners" although they do not change blood thickness or viscosity. Fig. 41-4 shows where in the blood clotting cascade these agents work.

Anticoagulant drugs work by interfering with one or more steps involved in the blood clotting cascade. Thus these agents prevent new clots from forming and limit or prevent extension of formed clots. *Anticoagulants do not break down existing clots.* These drugs are classified as thrombin inhibitors, vitamin K antagonists, and indirect factor X inhibitors.

Fibrinolytic drugs (also known as *thrombolytic drugs* or "clot busters") selectively break down fibrin threads present in formed blood clots. The mechanism to start fibrin

TABLE 41-3 DRUGS IMPAIRING THE HEMATOLOGIC SYSTEM

Drugs Causing Bone Marrow Suppression

- Altretamine
- Amphotericin B
- Azathioprine
- Chemotherapeutic agents
- Chloramphenicol
- Chronic phosphate
- Colchicine
- Didanosine
- Eflornithine
- Foscarnet sodium
- Ganciclovir
- Interferon alfa
- Pentamidine
- Sodium iodide
- Zalcitabine
- Zidovudine

Drugs Causing Hemolysis

- Acetohydroxamic acid
- Amoxicillin
- Chlorpropamide
- Doxapram
- Glyburide
- Mefenamic acid
- Menadiol diphosphate
- Methyl dopa
- Nitrofurantoin
- Penicillin G benzathine
- Penicillin V
- Primaquine
- Procainamide hydrochloride
- Quinidine polygalacturonate
- Quinine
- Sulfonamides
- Tolbutamide
- Vitamin K

Drugs Disrupting Platelet Action

- Aspirin
- Carbenicillin
- Carindacillin
- Dipyridamole
- Ibuprofen
- Moxalactam
- Naproxen
- Oxaprozin
- Pentoxifylline
- Sulfipyrazone
- Ticarcillin
- Ticlopidine
- Valproic acid

degradation is activation of the inactive tissue protein *plasminogen* to its active form, *plasmin*. Plasmin directly attacks and degrades the fibrin molecule.

The use of fibrinolytic drugs results in the best clot breakdown with less disruption of blood clotting. These drugs are the first-line therapy for problems caused by small, localized formed clots such as myocardial infarction (MI), limited arterial thrombosis, and thrombotic strokes. For some problems, such as MI, these drugs are usually given only within the first 6 hours after the onset of symptoms. This time limitation is not related to drug activity because fibrinolytic agents can break down clots older than 6 hours. Rather, the tissue that has been anoxic for more than 6 hours as a result of an acute event is not likely to benefit from this therapy, making the risks to the patient greater than the advantages.

Platelet inhibitors, or anti-platelet drugs, prevent either platelet activation or aggregation (clumping). The most widely used drug for this effect is aspirin, which inhibits the production of substances that activate platelets, such as thromboxane. Other drugs change the platelet membrane, reducing its “stickiness,” or prevent activators from binding to platelet receptors. In addition, many complementary therapy agents, such as St. John’s wort, inhibit platelet activity.

Nutrition Status

Diet can alter cell quality and affect blood clotting. Ask patients to record everything eaten during the previous week. Use this information to determine the causes of anemias and of protein, mineral, or vitamin deficiencies. Diets high in fat and carbohydrates and low in protein, iron, and vitamins can

cause many types of anemia and decrease the functions of all blood cells.

Ask about alcohol consumption because chronic alcoholism causes nutritional deficiencies and impairs the liver, both of which reduce blood clotting.

Certain dietary habits can enhance blood clotting. Diets high in vitamin K, found in leafy green vegetables, may increase the rate of blood clotting. Assess the amount of salads and other raw vegetables that the patient eats and whether supplemental vitamins and calcium are used. Assess the patient’s ability to understand and follow instructions related to procedures and tests, and prescribed drugs or diets. Ask about personal resources, such as finances and social support. A person with a poor income may have a diet low in iron and protein because food sources of these substances are often more expensive.

Family History and Genetic Risk

An accurate family history is important because many disorders affecting blood and blood clotting are inherited (Nussbaum et al., 2007). Ask whether anyone in the family has had hemophilia, frequent nosebleeds, postpartum hemorrhages, excessive bleeding after tooth extractions, or heavy bruising after relatively mild trauma. Ask whether any family member has sickle cell disease or sickle cell trait. Although sickle cell disease is seen most often among African Americans, anyone can have the trait.

Current Health Problems

Ask about lymph nodes swelling, excessive bruising or bleeding, and whether the bleeding was spontaneous or induced by trauma. Ask about the amount and duration of bleeding after routine dental work. Determine whether a woman has *menorrhagia* (excessive menstrual flow). Ask her to estimate the number of pads or tampons used during the most recent menstrual cycle and whether this amount represents a change from her usual pattern of flow. Ask whether clots are present in menstrual blood. If menstrual clots occur, ask her to estimate clot size using coins or fruit for comparison (“clots are dime-size” or “clots are the size of lemons”).

Assess and record whether the patient has shortness of breath on exertion, palpitations, frequent infections, fevers, recent weight loss, headaches, or paresthesias. Any or all of these symptoms may occur with hematologic disease.

The single most common symptom of anemia is fatigue. This problem occurs because oxygen delivery to cells is less than oxygen needs. Cells use oxygen to produce the high-energy chemical *adenosine triphosphate* (ATP) needed to perform most cellular work. When oxygen delivery to cells is reduced, cellular work decreases and fatigue increases. Ask patients about feeling tired, needing more rest, or losing endurance during normal activities. Ask them to compare their activities during the past month with those of the same month a year ago. Determine whether other symptoms of anemia, such as vertigo, tinnitus, and a sore tongue, are present.

Physical Assessment

Assess the whole body because blood problems may reduce oxygen delivery and tissue perfusion to all systems. Some assessment findings associated with hematologic problems are less reliable when seen in the older adult (see [Chart 41-1](#)). Equipment needed for assessment of hematologic function

includes gloves, a stethoscope, a blood pressure cuff, a tongue depressor, and a penlight.

Skin Assessment

Inspect the skin and mucous membranes for pallor or jaundice. Assess nail beds for pallor or cyanosis. Pallor of the gums, conjunctivae, and palmar creases (when the palm is stretched) indicates decreased hemoglobin levels and poor tissue oxygenation. Assess the gums for active bleeding in response to light pressure or brushing the teeth with a soft-bristled brush, and assess any lesions or draining areas. Inspect for petechiae and large bruises (*ecchymoses*). **Petechiae** are pinpoint hemorrhagic lesions in the skin. Bruises may cluster together. For hospitalized patients, determine whether there is bleeding from sites such as around nasogastric tubes, endotracheal tubes, central lines, peripheral IV sites, or Foley catheters. Check the skin turgor, and ask about itching because dry skin or itching can indicate hematologic disease. Assess body hair distribution patterns. Areas with poor circulation, especially the lower legs and toes, may have sparse or absent hair, although this may be a normal finding in an older adult.

CULTURAL AWARENESS

Pallor and cyanosis are more easily detected in people with darker skin by examining the oral mucous membranes and the conjunctiva of the eye. Jaundice can be seen more easily on the roof of the mouth. Petechiae may be visible only on the palms of the hands or the soles of the feet. Bruises can be seen as darker areas of skin and palpated as slight swellings or irregular skin surfaces. Ask the patient about pain when skin surfaces are touched lightly or palpated. (Chapter 26 provides tips for assessing darker skin.)

Head and Neck Assessment

Check for pallor or ulceration of the mouth mucosa. The tongue may be completely smooth in pernicious anemia and iron deficiency anemia or smooth and beefy red in nutritional deficiencies. These manifestations may occur with fissures at the corners of the mouth. Assess for jaundice of the sclera.

Inspect and palpate all lymph node areas. Document any lymph node enlargement, including whether palpation of the enlarged node causes pain and whether the enlarged node moves or remains fixed with palpation.

Respiratory Assessment

When blood problems reduce oxygen delivery, the lungs work harder to make adjustments that can maintain tissue perfusion. Assess the rate and depth of respiration while the patient is at rest, as well as during and after mild physical activity (e.g., walking 20 steps in 10 seconds). Note whether the patient can complete a 10-word sentence without stopping for a breath. Assess whether the patient is fatigued easily, has shortness of breath at rest or on exertion, or needs extra pillows to breathe well at night. Anemia can cause these symptoms as a result of respiratory changes made as adjustments to reduced tissue oxygen levels.

Cardiovascular Assessment

When blood problems reduce oxygen delivery, the heart works harder to make adjustments to maintain tissue perfusion. Pulses may become weak and thready. Observe for

distended neck veins, edema, or signs of phlebitis. Use a stethoscope to listen for murmurs, gallops, irregular rhythms, and abnormal blood pressure (BP). Systolic BP tends to be lower than normal in patients with anemia and higher than normal when the patient has excessive red blood cells. Severe anemia can cause heart enlargement and heart disease as the heart tries to compensate for reduced oxygen delivery.

Kidney and Urinary Assessment

The kidneys have many blood vessels, and bleeding problems may cause gross or occult *hematuria* (blood in the urine). Inspect urine for color. Hematuria may appear as grossly bloody red or dark brownish gold urine. Test the urine for proteins with a urine test dipstick because blood contains protein, and blood in the urine increases its protein content.

Musculoskeletal Assessment

Rib or sternal tenderness may occur with leukemia (cancer of the blood) when the bone marrow greatly overproduces cells, increasing the pressure in the bones. Examine the skin over superficial bones, including the ribs and sternum, by applying firm pressure with the fingertips. Assess the range of joint motion, and document any swelling or joint pain.

Abdominal Assessment

The normal adult spleen is usually *not* palpable. An enlarged spleen, however, occurs with many hematologic problems. An enlarged spleen may be detected by palpation. The spleen lies just beneath the abdominal wall, under the ribs on the left side. When it is enlarged, the spleen can be identified by its movement during respiration. Have the patient lie in a relaxed, supine position while you stand on the patient's right and palpate the left upper quadrant. *Palpate gently and cautiously because an enlarged spleen may be tender and easily ruptured.*

Palpating the edge of the liver in the right upper quadrant of the abdomen can detect hepatic enlargement, which often occurs with hematologic problems. The normal liver may be palpable as much as 4 to 5 cm below the right costal margin but is usually not palpable in the epigastrium.

A common cause of anemia among older adults is a chronically bleeding GI ulcer or polyp. If the ulcer is located in the stomach or the small intestine, obvious blood may not be visible in the stool or such a small amount is passed each day that the patient is not aware of it. Obtain a stool specimen for occult blood testing.

Central Nervous System Assessment

Examination of cranial nerves and testing neurologic function are important in hematologic assessment because some problems cause specific changes. Vitamin B₁₂ deficiency impairs cerebral, olfactory, spinal cord, and peripheral nerve

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which clinical manifestation reported by a client suggests to the nurse that anemia is a possibility?

- A. Difficulty sleeping
- B. Cold hands and feet
- C. Chronic headaches
- D. Shortness of breath

function, and severe chronic deficiency may cause permanent neurologic degeneration. Many neurologic problems can develop in patients who have leukemia, because leukemia can cause bleeding, infection, or tumor spread within the brain. When the patient with a suspected bleeding disorder has any head trauma, expand the assessment to include frequent neurologic checks and mental status examinations (see Chapter 43).

Psychosocial Assessment

The patient with hematologic problems may have a chronic illness (e.g., hemophilia or cancer) or an acute episode of a chronic disease (e.g., pernicious anemia). In either case, each person brings his or her own coping style to the illness. Develop a rapport with the patient and learn what coping mechanisms he or she has used successfully in the past.

Ask the patient and family members about social support networks and financial resources. A problem in these areas can interfere with the patient's adherence to therapy.

Diagnostic Assessment

Laboratory Assessment

In hematologic disease, the most definitive signs are often the laboratory test results. Chart 41-3 lists laboratory data used to assess hematologic function.

Tests of Cell Number and Function. A *peripheral blood smear* is made by taking a drop of blood and spreading it over a slide. It can be read by an automated calculator or by a technologist with a microscope. This rapid test can provide important information on the sizes, shapes, and approximate proportions of different blood cell types within the peripheral blood.

A *complete blood count (CBC)* includes a number of studies: red blood cell (RBC) count, white blood cell (WBC) count, hematocrit, and hemoglobin level. The RBC count measures circulating RBCs in 1 mm^3 of blood. The WBC count measures all leukocytes present in 1 mm^3 of blood. To determine the percentages of different types of leukocytes circulating in the blood, a WBC count with differential leukocyte count is performed (see Chapter 19). The hematocrit (Hct) is calculated as the percentage of red blood cells in the total blood volume. The hemoglobin level is the total amount of hemoglobin in blood.

The CBC can measure other features of the RBCs, including mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). MCV measures the average volume or size of a single RBC and is useful for classifying anemias. When the MCV is elevated, the cell is larger than normal (*macrocytic*), as seen in megaloblastic anemias. When the MCV is decreased, the cell is smaller than normal (*microcytic*), as seen in iron deficiency anemia. The MCH is the average amount of hemoglobin by weight in a single RBC. The MCHC measures the average amount of hemoglobin by percentage in a single RBC. When the MCHC is decreased, the cell has a hemoglobin deficiency and is *hypochromic* (a lighter color), as in iron deficiency anemia (Miller & Starks, 2010).

Reticulocyte count is another hematologic test helpful in determining bone marrow function. A reticulocyte is an immature RBC that still has its nucleus. An elevated reticulocyte count indicates that RBCs are being produced and

released by the bone marrow before they mature. Normally only about 2% of circulating RBCs are reticulocytes. An elevated reticulocyte count is desirable in an anemic patient or after hemorrhage because this indicates that the bone marrow is responding appropriately to a decrease in the total RBC level. An elevated reticulocyte count without a precipitating cause usually indicates health problems, such as polycythemia vera (a malignant condition in which the bone marrow overproduces RBCs).

A *platelet count*, also known as a thrombocyte count, is performed on venous blood that is placed in the same type of lavender-top tube used for a complete blood count. The normal range is 150,000 to 400,000/ mm^3 and reflects the number of platelets in circulation. When this value is low (thrombocytopenia), the person is at a greater risk for bleeding because platelets are critical for blood clotting. Patients who have values between 40,000/ mm^3 and 80,000/ mm^3 may have prolonged bleeding from trauma, dental work, and surgery. Patients who have platelet values below 20,000/ mm^3 may have spontaneous bleeding that is very difficult to stop.

Hemoglobin electrophoresis detects abnormal forms of hemoglobin, such as hemoglobin S in sickle cell disease. Hemoglobin A is the major type of hemoglobin in an adult. Decreased hemoglobin A levels with increasing levels of other types of hemoglobin indicate some hematologic problems, such as sickle cell disease.

Leukocyte alkaline phosphatase (LAP) is an enzyme produced by normal mature neutrophils. Elevated LAP levels occur during episodes of infection or stress. An elevated neutrophil count without an elevation in LAP level occurs with some types of leukemia.

Coombs' tests, both direct and indirect, are used for blood typing. The direct test detects antibodies against RBCs that may be attached to a person's RBCs. Although healthy people can make these antibodies, in certain diseases (e.g., systemic lupus erythematosus, mononucleosis) these antibodies are directed against the patient's own RBCs. The presence of these antibodies can cause hemolytic anemia (Matthews & Newton, 2010).

The indirect Coombs' test detects the presence of circulating antiglobulins. The test is used to determine whether the patient has serum antibodies to the type of RBCs that he or she is about to receive by blood transfusion (Matthews & Newton, 2010).

Serum ferritin, transferrin, and the total iron-binding capacity (TIBC) tests measure iron levels. Abnormal levels of iron and TIBC occur with problems such as iron deficiency anemia.

The serum ferritin test measures the amount of free iron present in the plasma. The amount of serum ferritin is related to the amount of intracellular iron and represents 1% of the total body iron stores. Therefore the serum ferritin level provides a means to assess total iron stores. People with serum ferritin levels within 10 g of the normal range for their gender have adequate iron stores; people with levels 10 g or more lower than the normal range have inadequate iron stores and have difficulty recovering from any blood loss.

Transferrin is a protein that transports dietary iron from the intestines to cell storage sites. Transferrin is not easily measured, but measuring the amount of iron that can be bound to serum transferrin indirectly determines whether an

CHART 41-3 LABORATORY PROFILE

Hematologic Assessment

TEST	REFERENCE RANGE	INTERNATIONAL REFERENCE UNITS	SIGNIFICANCE OF ABNORMAL FINDINGS
Red blood cell (RBC) count	<i>Females:</i> 4.2-5.4 million/ μ L <i>Males:</i> 4.7-6.1 million/ μ L	$4.2-5.4 \times 10^{12}$ cells/L $4.7-6.1 \times 10^{12}$ cells/L	<i>Decreased levels</i> indicate possible anemia or hemorrhage. <i>Increased levels</i> indicate possible chronic hypoxia or polycythemia vera.
Hemoglobin (Hgb)	<i>Females:</i> 12-16 g/dL <i>Males:</i> 14-18 g/dL	7.4-9.9 mmol/L 8.7-11.2 mmol/L	Same as for RBC.
Hematocrit (Hct)	<i>Females:</i> 37%-47% <i>Males:</i> 42%-52%	0.37-0.47 fraction 0.42-0.52 fraction	Same as for RBC.
Mean corpuscular volume (MCV)	80-95 fL	Same as reference range	<i>Increased levels</i> indicate macrocytic cells, possible anemia. <i>Decreased levels</i> indicate microcytic cells, possible iron deficiency anemia.
Mean corpuscular hemoglobin (MCH)	27-31 pg	Same as reference range	Same as for MCV.
Mean corpuscular hemoglobin concentration (MCHC)	32-36 g/dL	320-370 g/L	<i>Increased levels</i> may indicate spherocytosis or anemia. <i>Decreased levels</i> may indicate iron deficiency anemia or a hemoglobinopathy.
White blood cell (WBC) count	5000-10,000/mm ³	$5.0-10.0 \times 10^9$ cells/L	<i>Increased levels</i> are associated with infection, inflammation, autoimmune disorders, and leukemia. <i>Decreased levels</i> may indicate prolonged infection or bone marrow suppression.
Reticulocyte count	0.5%-2.0% of RBCs	0.005-0.20 fraction	<i>Increased levels</i> may indicate chronic blood loss. <i>Decreased levels</i> indicate possible inadequate RBC production.
Total iron-binding capacity (TIBC)	250-460 mcg/dL	45-82 μ mol/L	<i>Increased levels</i> indicate iron deficiency. <i>Decreased levels</i> may indicate anemia, hemorrhage, hemolysis.
Iron (Fe)	<i>Females:</i> 60-160 mcg/dL <i>Males:</i> 80-180 mcg/dL	11-29 μ mol/L 14-32 μ mol/L	<i>Increased levels</i> indicate iron excess, liver disorders, hemochromocytosis, megaloblastic anemia. <i>Decreased levels</i> indicate possible iron deficiency anemia, hemorrhage.
Serum ferritin	<i>Females:</i> 10-150 ng/mL <i>Males:</i> 12-300 ng/mL	10-150 mcg/L 12-300 mcg/L	Same as for iron.
Platelet count	150,000-400,000/mm ³	$150-400 \times 10^9$ /L	<i>Increased levels</i> may indicate polycythemia vera or malignancy. <i>Decreased levels</i> may indicate bone marrow suppression, autoimmune disease, hypersplenism.
Hemoglobin electrophoresis	Hgb A ₁ : 95%-98% Hgb A ₂ : 2%-3% Hgb F: 0.8%-2% Hgb S: 0% Hgb C: 0%	Same as reference range	<i>Variations</i> indicate hemoglobinopathies.
Direct Coombs' and indirect Coombs' test	Negative	Negative	<i>Positive findings</i> indicate antibodies to RBCs.
Prothrombin time (PT)	11-12.5 sec	Patient PT/normal PT INR 0.8-1.1	<i>Increased time</i> indicates possible deficiency of clotting factors V and VII. <i>Decreased time</i> may indicate vitamin K excess.

fL, femtoliter; INR, international normalized ratio; pg, picograms.

adequate amount of transferrin is present. This test is the total iron-binding capacity (TIBC) test. In healthy people, only about 30% of the transferrin is bound to iron in the blood. TIBC is measured by taking a sample of blood and adding measured amounts of iron to it. TIBC is calculated when the blood no longer binds the iron but allows it to precipitate. TIBC increases when a person is deficient in serum iron and stored iron levels. Such a value indicates that

an adequate amount of transferrin is present but less than 30% of it is bound to serum iron.

Tests Measuring Bleeding and Coagulation. Tests that measure bleeding and coagulation provide information that reflects the effectiveness of different aspects of the blood clotting. These tests are used for diagnosis of specific hematologic health problems, determination of drug therapy effectiveness, and identification of risk for excessive bleeding or clotting.

Prothrombin time (PT) measures how long blood takes to clot. This test reflects the level of clotting factors II, V, VII, and X and how well they are functioning. When enough of these clotting factors are present and functioning, the PT shows blood clotting between 11 and 12.5 seconds or within 85% to 100% of the time needed for a control sample of blood to clot. PT is prolonged when one or more of these clotting factors are deficient. Warfarin (Coumadin, Warfilone ☛) therapy is also monitored using PT levels. Usually warfarin therapy is considered appropriate when the PT is prolonged by 1.5 to 2 times the patient's normal PT value, depending on the specific reason for the warfarin therapy.

The PT test is now used less often to assess how fast blood clots, because control blood is taken from different people and may not be the same even in one laboratory from one day to the next. To reduce PT errors from control blood variation or in some of the chemicals used in the test, the international normalized ratio is used to assess clotting time.

International normalized ratio (INR) measures the same process as the PT by establishing a normal mean or standard for PT. The INR is calculated by dividing the patient's PT by the established standard PT. A normal INR ranges between 0.7 and 1.8. When using the INR to monitor warfarin therapy, the desired outcome is usually to maintain the patient's INR between 2.0 and 3.0 regardless of the actual PT in seconds. The desired INR range for any patient, however, is individualized for specific patient factors and medical conditions (Weyland, 2009).

The partial thromboplastin time (PTT) assesses the intrinsic clotting cascade and the action of factors II, V, VIII, IX, XI, and XII. PTT is prolonged whenever any of these factors is deficient, such as in hemophilia or disseminated intravascular coagulation (DIC). Because factors II, IX, and X are vitamin K-dependent and are produced in the liver, liver disease can prolong the PTT. Unfractionated heparin (Calci-parin, Hepalean ☛) therapy is often monitored by PTT or the anti-factor Xa test. Desired therapeutic ranges for anticoagulation are usually between 1.5 and 2.0 times normal values but can be greater depending on the reason the person is receiving anticoagulation therapy.

The anti-factor Xa test measures the amount of anti-activated factor X (anti-Xa) in blood, which is affected by heparin. It is used mainly to monitor heparin levels in patients treated with either unfractionated heparin or low molecular weight heparin. For people not receiving heparin in any form, the reference range is less than 0.1 IU/mL. The usual therapeutic range for patients receiving standard heparin is 0.5 to 1.0 IU/mL, and the usual therapeutic range for patients receiving low molecular weight heparin is 0.3 to 0.7 IU/mL. Test results are affected by age, gender, health history, and the specific laboratory technique used for the test.

Platelet aggregation, or the ability to clump, is tested by mixing the patient's plasma with an agonist substance that should cause clumping. Agonists used include collagen, epinephrine, adenosine diphosphate, and ristocetin. The degree of clumping is noted. Aggregation can be impaired in von Willebrand's disease and by drugs such as aspirin, anti-inflammatory agents, psychotropics, and platelet inhibitors.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which laboratory blood test result for a client undergoing hematologic assessment does the nurse report immediately to the prescriber?

- A. Red blood cell count 1.2 million/mm³
- B. Platelets 185,000/mm³
- C. Hematocrit 36%
- D. INR 1.2

Imaging Assessment

Assessment of the patient with a suspected hematologic problem can include radioisotopic imaging. Isotopes are used to evaluate the bone marrow for sites of active blood cell formation and sites of iron storage. Radioactive colloids are used to determine organ size and liver and spleen function.

The patient is given a radioactive isotope by IV about 3 hours before the procedure. Once in the nuclear medicine department, he or she must lie still for about an hour during the scan. No special patient preparation or follow-up care is needed for these tests.

Standard x-rays may be used to diagnose some hematologic problems. For example, multiple myeloma causes classic bone destruction, with a "Swiss cheese" appearance on x-ray.

Bone Marrow Aspiration and Biopsy

Bone marrow aspiration or biopsy, which are similar invasive procedures, are performed to evaluate the patient's hematologic status when other tests show persistent abnormal findings that indicate a possible problem in blood cell production or maturation. Results provide information about bone marrow function, including the production of all blood cells and platelets. In a bone marrow aspiration, cells and fluids are suctioned from the bone marrow. In a bone marrow biopsy, solid tissue and cells are obtained by coring out an area of bone marrow with a large-bore needle.

A health care provider's order and a signed informed consent are obtained before either procedure is performed. Bone marrow aspiration may be performed by a physician, an advanced practice nurse, or a physician assistant, depending on the agency's policy and regional law. The procedure may be performed at the patient's bedside, in an examination room, or in a laboratory.

After learning what specific tests will be performed on the marrow, check the facility's procedure manual and the hematology laboratory to determine how to handle the specimen. Some tests require that heparin or other solutions be added to the specimen.

Patient Preparation. Most patients are anxious before a bone marrow aspiration, even those who have had one in the past. You can help reduce anxiety and allay fears by providing accurate information and emotional support (Beattie, 2007). Some patients like to have their hand held during the procedure.

Explain the procedure, and reassure the patient that you will stay during the entire procedure. Occasionally a friend or family member is permitted to be present to hold the patient's hand and provide emotional support. Tell the patient that the local anesthetic injection will feel like a stinging or burning sensation. Tell him or her to expect a heavy sensation of pressure and pushing while the needle is being inserted.

Sometimes a crunching sound can be heard or scraping sensation felt as the needle punctures the bone. Explain that a brief sensation of painful pulling will be experienced as the marrow is being aspirated by mild suction in the syringe. If a biopsy is performed, the patient may feel more pressure and discomfort as the needle is rotated into the bone.

Assist the patient onto an examining table, and expose the site (usually the iliac crest). If this site is not available or if more marrow is needed, the sternum can be used. If the iliac crest is the site, place the patient in the prone or side-lying position. Depending on the tests to be performed on the specimen, a laboratory technician may also be present to ensure proper handling of the specimen.

Procedure. The procedure usually lasts from 5 to 15 minutes. The type and the amount of anesthesia or sedation depend on the physician's preference, the patient's preference and previous experience with bone marrow aspiration and biopsy, and the setting.

A local anesthetic agent is injected into the skin around the site. The discomfort of the local anesthetic is reduced when buffered anesthetic agents, such as lidocaine, are used (Ruegg et al., 2009). The patient may also receive a mild tranquilizer or a rapid-acting sedative, such as midazolam (Versed), lorazepam (Ativan, Apo-Lorazepam 🍁, Novo-Lorazem 🍁), or etomidate (Amidate). Some patients do well with guided imagery or autohypnosis.

! NURSING SAFETY PRIORITY

Action Alert

Aspiration or biopsy procedures are invasive, and sterile precautions are observed.

The skin over the site is cleaned with a disinfectant. For an aspiration, the needle is inserted with a twisting motion and the marrow is aspirated by pulling back on the plunger of the syringe. When sufficient marrow has been aspirated to ensure accurate analysis, the needle is rapidly withdrawn while the tissues are supported at the site. For a biopsy, a small skin incision is made and the biopsy needle is inserted through the skin opening. Pressure and several twisting

motions are needed to ensure coring and loosening of an adequate amount of marrow tissue. Apply external pressure to the site until hemostasis is ensured. A pressure dressing or sandbags may be applied to reduce bleeding at the site.

Follow-Up Care. The nursing priority after a bone marrow aspiration or biopsy is prevention of excessive bleeding. Cover the site with a dressing after bleeding is controlled, and closely observe it for 24 hours for signs of bleeding and infection. A mild analgesic (aspirin-free) may be given for discomfort, and ice packs can be placed over the site to limit bruising. Instruct the patient to inspect the site every 2 hours for the first 24 hours and to note the presence of active bleeding or bruising. Advise him or her to avoid contact sports or any activity that might result in trauma to the site for 48 hours.

Information obtained from bone marrow aspiration or biopsy reflects the degree and quality of bone marrow activity present. The counts made on a marrow specimen can indicate whether different cell types are present in the expected quantities and proportions. In addition, bone marrow aspiration or biopsy can confirm the spread of cancer cells from other tumor sites.

DECISION-MAKING CHALLENGE

Safety; Patient-Centered Care

The patient is a 28-year-old intensive care nurse who is scheduled to have a bone marrow biopsy tomorrow because of persistently low red blood cell and platelet counts and a persistently higher-than-normal white blood cell count. While making the arrangements today, she tells you that she is planning on having the biopsy on her lunch break tomorrow and going back to work afterward to complete the last 6 hours of her 12-hour shift. She says that she is beginning a 10-day work stretch and cannot afford to take time off. If it isn't possible for her to have the biopsy done during lunch tomorrow, she will have to put it off for about 2 weeks. Her usual medications include two 325-mg aspirins daily for general aches and pain and her oral contraceptive.

1. What should you tell her about having a bone marrow biopsy on her lunch break?
2. Is delaying the biopsy for 2 weeks a wise decision? Explain why or why not.
3. What will you tell her about continuing her normal medications?

NURSING CONCEPT REVIEW

What should you expect to NOTICE in a patient with adequate oxygenation and tissue perfusion related to hematologic function?

Vital signs

- Heart rate and respiratory rate within normal range
- Blood pressure within normal range

Physical assessment

- Able to speak a sentence of 12 words without stopping for breath
- Able to walk and talk without stopping for breath
- Skin color normal (no cyanosis, pallor, or jaundice)

- Oral mucous membrane and nail beds pink with rapid capillary refill
- Gums pink, no petechiae or bleeding
- Appropriate distribution of body hair, especially on legs and feet
- Warm hands and feet, no dependent edema
- Creases on palms of the hand (when stretched) red (or brown in people with dark skin)
- Skin clear with no large bruises or petechiae
- Lower eyelid conjunctive red
- Urine output just about equal to fluid intake
- Urine clear and yellow

NURSING CONCEPT REVIEW—cont'd*Psychological assessment*

- Oriented and not confused
- Energy level good; able to engage in desired work and recreational and personal activities

Laboratory assessment

- Red blood cell, hemoglobin, hematocrit, white blood cell, and platelet levels within normal limits for age and gender
- Reticulocyte count less than 2%

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Verify that a patient having a bone marrow aspiration or biopsy has signed an informed consent statement.

Health Promotion and Maintenance

- Teach people to avoid unnecessary contact with environmental chemicals or toxins. If contact cannot be avoided, teach people to use safety precautions.
- Instruct patients about the importance of eating a diet with adequate amounts of foods that are good sources of iron, folic acid, and vitamin B₁₂.

Psychosocial Integrity

- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Ask patients about their activity level and whether they are satisfied with the energy they have for activities.

- Support the patient during a bone marrow aspiration or biopsy.

Physiological Integrity

- Tissue oxygenation and perfusion rely on normal hematologic function for oxygen delivery.
- The most common manifestation of a hematologic problem is fatigue.
- Remember that a platelet plug and a fibrin clot are not the same.
- Understand the effects of age and gender on red blood cell, hematocrit, and hemoglobin levels.
- Apply an ice pack to the needle site after a bone marrow aspiration or biopsy.
- Check the needle site at least every 2 hours after a bone marrow aspiration or biopsy. If the patient is going home, teach the patient and family how to assess the site for bleeding and when to seek help.
- Instruct patients to avoid activities that may traumatize the site after a bone marrow aspiration or biopsy.

Care of Patients with Hematologic Problems

Concept Map Creator
Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Examine individual patient factors for threats to safety, especially among older adults.
2. Apply the principles of asepsis to protect immunocompromised patients.
3. Modify the environment to protect patients who have thrombocytopenia.
4. Identify appropriate community resources for the patient with a serious hematologic problem or recovering from a stem cell transplant.
5. Plan continuity of care between the hospital and community-based agencies for the patient having a stem cell transplant.
6. Verify patient identification before any form of transfusion therapy.

Health Promotion and Maintenance

7. Teach patients ways to prevent leukemia or lymphoma by avoiding known environmental causative agents.
8. Identify patients at increased risk for infection and hemorrhage.
9. Assess the patient's endurance in performing ADLs.
10. Coordinate with a dietitian to teach patients with dietary deficiency-related anemia about the appropriate food sources for anemia prevention.
11. Teach patients and family members how to avoid injury and infection when blood counts are low.

Psychosocial Integrity

12. Encourage the patients and family members to express their feelings about the diagnosis of a serious hematologic problem, its prognosis, and treatment.
13. Use effective communication when teaching patients and family members about what to expect during tests and therapeutic procedures.
14. Use complementary and alternative therapies along with drug therapy to improve patient comfort.

Physiological Integrity

15. Identify three clinical manifestations common to patients who have any type of anemia.
16. Identify people at increased genetic risk for a hematologic disorder.
17. Prioritize nursing care for the patient who has sickle cell disease.
18. Identify the risk factors for the development of leukemia, lymphoma, and myelodysplastic syndromes.
19. Interpret laboratory data and clinical manifestations to determine the presence of infection in a patient who has neutropenia.
20. Prioritize nursing interventions for the patient with neutropenia.
21. Prioritize nursing interventions for the patient with thrombocytopenia.
22. Prioritize nursing responsibilities during transfusion therapy.
23. Identify patients at risk for complications of transfusion therapy.

Hematologic problems result from the impaired production, the impaired function, or the abnormal destruction of any type of blood cell. Problems of the hematologic system can affect many tissues and organs by interfering with *oxygenation and tissue perfusion*. The type and severity of the disorder determine the impact it has on the health of patients. This chapter discusses mild hematologic disorders and those that are potentially life threatening, such as sickle cell disease and leukemia.

RED BLOOD CELL DISORDERS

Red blood cells (RBCs), also known as **erythrocytes**, are the major cell in the blood. *Tissue oxygenation* depends on keeping the circulating number of RBCs within the normal range for the person's age and gender. It also depends on the ability of RBCs to perform their normal functions. RBC disorders include problems in production, function, and destruction. Problems may result in poor function of RBCs, decreased numbers of RBCs (**anemia**), or an excess of RBCs (**polycythemia**).

ANEMIA

Anemia is a reduction in either the number of RBCs, the amount of hemoglobin, or the **hematocrit** (percentage of packed RBCs per deciliter of blood). It is a clinical sign, not a specific disease, because it occurs with many health problems. Anemia can result from dietary problems, genetic disorders, bone marrow disease, or excessive bleeding. GI bleeding is the most common reason for anemia in adults.

There are many types and causes of anemia. Some are caused by a deficiency in one or more of the components needed to make fully functional RBCs. Such anemias can be caused by deficiencies of iron, vitamin B₁₂, folic acid, or intrinsic factor. Other causes include a decreased rate of RBC production and increased RBC destruction. Table 42-1 lists common causes of many anemias. Despite the many causes of anemia, the effects of anemia on the patient (Chart 42-1) and the nursing care needed are similar for all types of anemia (Coyer & Lash, 2008).

ANEMIAS RESULTING FROM INCREASED DESTRUCTION OF RED BLOOD CELLS

SICKLE CELL DISEASE

Pathophysiology

Sickle cell disease (SCD), which used to be called *sickle cell anemia*, is a genetic disorder that results in chronic anemia, pain, disability, organ damage, increased risk for infection, and early death. There is a difference between sickle cell disease state and sickle cell trait. In addition, there is great variation among patients in how severe the disease is and when complications start.

The main problem in this disorder is the formation of abnormal hemoglobin chains. In healthy adults, the normal hemoglobin molecule has two alpha chains and two beta chains of amino acids. Normal adult hemoglobin is called **hemoglobin A (HbA)**. Normal adult red blood cells usually contain 98% to 99% HbA, with a small percentage of a fetal form of hemoglobin (HbF).

TABLE 42-1 COMMON CAUSES OF ANEMIA

TYPE OF ANEMIA	COMMON CAUSES
Sickle cell disease	Autosomal recessive inheritance of two defective gene alleles for hemoglobin synthesis
Glucose-6-phosphate dehydrogenase (G6PD) deficiency anemia	X-linked recessive deficiency of the enzyme <i>G6PD</i>
Autoimmune hemolytic anemia	Abnormal immune function in which a person's immune reactive cells fail to recognize his or her own red blood cells as self cells
Iron deficiency anemia	Inadequate iron intake caused by: • Iron-deficient diet • Chronic alcoholism • Malabsorption syndromes • Partial gastrectomy Rapid metabolic (anabolic) activity caused by: • Pregnancy • Adolescence • Infection
Vitamin B ₁₂ deficiency anemia	Dietary deficiency Failure to absorb vitamin B ₁₂ from intestinal tract as a result of: • Partial gastrectomy • Pernicious anemia • Malabsorption syndromes
Folic acid deficiency anemia	Dietary deficiency Malabsorption syndromes Drugs: • Oral contraceptives • Anticonvulsants • Methotrexate
Aplastic anemia	Exposure to myelotoxic agents: • Radiation • Benzene • Chloramphenicol • Alkylating agents • Antimetabolites • Sulfonamides • Insecticides Viral infection (unproven): • Epstein-Barr virus • Hepatitis B • Cytomegalovirus

In SCD, at least 40% (and often much more) of the total hemoglobin is composed of an abnormality of the beta chains, known as *hemoglobin S (HbS)*. HbS is sensitive to changes in the oxygen content of the RBC. When RBCs having large amounts of HbS are exposed to decreased oxygen conditions, the abnormal beta chains contract and pile together within the cell, distorting the shape of the RBC. These cells assume a sickle shape, become rigid, and clump together, causing the RBCs to become "sticky" and fragile. These clumps form masses of sickled RBCs that block blood flow (Fig. 42-1). This blood vessel obstruction, known as a *vaso-occlusive event (VOE)*, leads to further tissue **hypoxia** (reduced oxygen supply) and more sickle-shaped cells, which then leads to more blood vessel obstruction and ischemia. Repeated episodes of ischemia lead to progressive organ

FIG. 42-1 Red blood cell actions under conditions of low tissue oxygenation. (HbA, Hemoglobin A; HbS, hemoglobin S.)

CHART 42-1 KEY FEATURES

Anemia

Integumentary Manifestations

- Pallor, especially of the ears, the nail beds, the palmar creases, the conjunctivae, and around the mouth
- Cool to the touch
- Intolerance of cold temperatures
- Nails become brittle and may lose the normal convex shape; over time, nails become concave and fingers assume clublike appearance

Cardiovascular Manifestations

- Tachycardia at basal activity levels, increasing with activity and during and immediately after meals
- Murmurs and gallops heard on auscultation when anemia is severe
- Orthostatic hypotension

Respiratory Manifestations

- Dyspnea on exertion
- Decreased oxygen saturation levels

Neurologic Manifestations

- Increased somnolence and fatigue
- Headache

damage from anoxia and infarction. Conditions that cause sickling include hypoxia, dehydration, infections, venous stasis, pregnancy, alcohol consumption, high altitudes, low or high environmental or body temperatures, acidosis, strenuous exercise, emotional stress, and anesthesia.

Usually, sickled cells go back to normal shape when the precipitating condition is removed, the blood oxygen level is normalized, and proper *tissue perfusion* resumes. Although the cells then appear normal, at least some of the hemoglobin remains twisted, decreasing cell flexibility. The cell membranes become damaged over time, and cells are permanently sickled. The membranes of cells with HbS are more fragile and more easily broken. The average life span of an RBC containing 40% or more of HbS is about 12 to 15 days, much less than the 120-day life span of normal RBCs. This reduced RBC life span causes **hemolytic** (blood cell–destroying) anemia in patients with sickle cell disease.

FIG. 42-2 Possible transmission of sickle cell disease and sickle cell trait when both parents are carriers.

The patient with SCD has periodic episodes of extensive cellular sickling, called **crises**. The crises have a sudden onset and can occur as often as weekly or as seldom as once a year. Many patients are in good health much of the time, with crises occurring only in response to conditions that cause local or systemic **hypoxemia** (deficient oxygen in the blood).

Repeated VOEs of larger blood vessels have long-term damaging effects on tissues and organs. Most effects occur as a result of tissue hypoxia, anoxia, ischemia, and cell death. Tissues and organs begin to have small infarcted areas and scar tissue formation. Eventually, so many healthy cells are destroyed that organ failure results. Tissues most often affected in this way are the spleen, liver, heart, kidney, brain, joints, bones, and retina.

Etiology and Genetic Risk

Sickle cell disease (SCD) is a genetic disorder with an autosomal recessive pattern of inheritance (see [Chapter 6](#)). The formation of the beta chains of hemoglobin depends on a pair of gene alleles (alternate forms of a gene). A mutation in these alleles leads to the formation of HbS instead of HbA. In sickle cell disease, the patient has two HbS gene alleles, one inherited from each parent, usually resulting in 80% to 100% of the total hemoglobin being HbS. Because both hemoglobin alleles are S, sickle cell disease is sometimes also abbreviated “SS.” Patients with SCD have severe manifestations of the disease even when triggering conditions are mild. If a patient with SCD has children, each child will inherit one of the two abnormal gene alleles and at least have sickle cell trait.

In **sickle cell trait**, one normal gene allele and one abnormal gene allele for hemoglobin are inherited, so that only half of the hemoglobin chains produced are abnormal. Because people with this problem have one hemoglobin A allele and one hemoglobin S allele, sickle cell trait is abbreviated “AS.” The patient is a carrier of the HbS gene allele ([Fig. 42-2](#)) and can pass the trait on to his or her children. However, the patient has only mild manifestations of the disease when precipitating conditions are present because less than 40% of the hemoglobin is abnormal.

Incidence/Prevalence

Sickle cell trait and different forms of SCD occur in people of all races and ethnicities but less often among white people. In the United States, about 70,000 people have SCD, most commonly in African Americans (U.S. National Library of Medicine [USNLM], 2011). SCD occurs in 1 in 500 African Americans, and 1 in 12 to 1 in 15 (8%) African Americans are carriers of one sickle cell gene allele and have AS (USNLM, 2011).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

An adult with sickle cell disease (SCD) usually has a long-standing diagnosis of the disorder. An adult with sickle cell trait usually has no hematologic manifestations or abnormal laboratory findings other than the presence of hemoglobin S. This person may be unaware that he or she has a hematologic problem until an acute illness is present or when anesthesia is administered.

Ask the patient about previous crises, what led to the crises, severity, and usual treatments. Explore recent contact with ill people and activities to determine what caused the current crisis. Ask him or her about symptoms of infection as the cause of a crisis, such as sore throat, cough, GI changes, or pain and burning upon urination.

Review all activities and events during the past 24 hours, including food and fluid intake, exposure to temperature extremes, drugs taken, exercise, trauma, stress, recent airplane travel, and ingestion of alcohol or other recreational drugs. Ask about changes in sleep and rest patterns, ability to climb stairs, and any activity that induces shortness of breath. Determine his or her perceived energy level using a scale ranging from 0 to 10 (0 = not tired with plenty of energy; 10 = total exhaustion) to assess the degree of fatigue. This activity review provides important information about fatigue, activity tolerance, and participation in ADLs. It may also help patients determine what specific types of activities or environmental changes trigger their crises.

Physical Assessment/Clinical Manifestations

Pain is the most common symptom of SCD crisis. Other manifestations vary with the site of tissue damage.

Cardiovascular changes, including the risk for high-output heart failure, occur because of the anemia. Assess the patient for shortness of breath and general fatigue or weakness. Other problems may include murmurs, the presence of an S₃ heart sound, and increased jugular-venous pulsation or distention. Assess his or her cardiac and vascular status by comparing peripheral pulses, temperature, and capillary refill in all extremities. Extremities distal to blood vessel occlusion are cool to the touch with slow capillary refill and may have reduced or absent pulses. Heart rate may be rapid and blood pressure low to average, with a decreased pulse pressure, because breakage of RBCs leads to anemia. Anemia results in a less viscous (thinner) blood that moves more rapidly through the heart and blood vessels under lower pressures than does blood with normal viscosity.

Priapism is a prolonged penile erection that can occur in men who have SCD. The cause is excessive vascular engorgement in erectile tissue. The condition is very painful and can last for hours. During the priapism episode, the patient usually cannot urinate.

Skin changes include pallor or cyanosis because of *poor oxygenation* from *decreased perfusion* and anemia. Examine the lips, tongue, nail beds, conjunctivae, palms, and soles of the feet at least every 8 hours for subtle color changes. With cyanosis, the lips and tongue are gray and the palms, soles, conjunctivae, and nail beds have a bluish tinge.

Another skin manifestation of SCD is jaundice. Jaundice results from RBC destruction and release of bilirubin. Bilirubin is present inside RBCs and released when fragile cells are damaged, leading to jaundice. To assess for jaundice in patients with darker skin, inspect the roof of the mouth for a yellow appearance. Yellow-tinged sclera may be misleading because of normal deposits of fat that appears yellowish in contrast to the dark skin around the eye. Examine the sclera closest to the cornea to assess jaundice more accurately. The palms and soles of dark-skinned patients may appear yellow if calloused and could be mistaken for jaundice. Jaundice often causes intense itching.

Despite the anemia, patients with SCD usually are not iron deficient. With increased RBC production and destruction, iron released from the cells increases the pigmentation of the skin.

As many as 75% of adults with SCD have open sores or ulcers on the lower legs that are caused by *poor tissue perfusion*. The outer sides and inner aspect of the ankle or the shin are common ulcer sites. Inspect the legs and feet for open lesions or darkened areas that may indicate necrotic tissue. These lesions often become necrotic or infected, requiring débridement and antibiotic therapy. Skin grafting may be needed when ulcers fail to heal.

Abdominal changes include major organ damage to the spleen and liver. These organs are usually the first to be damaged from many episodes of hypoxia and ischemia. In crisis, abdominal pain is diffuse and steady, involving the back and legs (Sickle Cell Information Center, 2010). Bowel sounds should be present with normal activity. Palpate the liver and spleen for enlargement. The liver or spleen may feel firm and enlarged with a nodular or “lumpy” texture in later stages of the disease. Check for guarding or rebound tenderness to palpation. A rapidly enlarging liver or spleen with increasing jaundice may indicate blood trapping in those organs.

Kidney and urinary changes are common as a result of *poor perfusion*. Chronic kidney disease occurs as a result of anoxic damage to the kidney nephrons. With early damage, the kidneys are less effective at filtration and reabsorption. The urine contains protein, and the patient may not concentrate urine. Eventually, the kidneys fail, resulting in little or no urine output. The buildup of waste products in the blood leads to death.

Musculoskeletal changes occur because arms and legs are common sites of blood vessel occlusion in SCD. Joints also may be damaged from hypoxic episodes and have necrotic degeneration. Inspect the arms and legs for symmetry, and record any areas of swelling, temperature, or color difference. Ask patients to move all joints. Record the range of motion and any pain with movement.

Central nervous system (CNS) changes may occur in SCD. During crises, patients may have a low-grade fever. If the CNS has infarcts or repeated episodes of hypoxia, patients may have seizures or manifestations of a stroke, including pronator drift and a weakened hand grasp. Assess for the presence of “pronator drift” by having the patient extend both arms in front in a palms up (supination) position. Pronator drift occurs when the patient cannot maintain one or both hands in the supine position and the hand drifts into a prone or palm-down position. Assess hand grasps on both sides. Also assess the patient’s gait and coordination.

Psychosocial Assessment

Psychosocial assessment is important because behavioral changes are early manifestations of cerebral hypoxia from *poor tissue perfusion*. Observe the patient, and document behavior. Ask family members whether the current behavior and mental status are usual for the patient.

SCD is a painful, life-limiting disorder that can be passed on to one’s children. Assess the patient’s psychosocial needs in terms of new factors, established support systems, use of coping patterns, and disease progression. Ask the patient about how he or she views the disease and what changes in lifestyle have been made as limitations increased.

Laboratory Assessment

The diagnosis of SCD is based on the percentage of hemoglobin S (HbS) on electrophoresis. A person who has AS usually has less than 40% HbS, and the patient with SCD may have 80% to 100% HbS. This percentage does not change during crises. Another indicator of SCD is the number of RBCs with permanent sickling. This value is less than 1% among people with no hemoglobin disease, is 5% to 50% among people with AS, and may be 90% among patients with SCD.

Other laboratory tests can indicate complications of the disease, especially during crises. The hematocrit of patients with SCD is low (between 20% and 30%) because the life span of the RBC is so much shorter than normal and because many cells are destroyed. This value decreases even more during crises or when the bone marrow fails to produce cells during stress (aplastic crisis). The reticulocyte count is high, indicating anemia of long duration. It is high because the bone marrow is releasing immature red blood cells (reticulocytes) to make up for the low hematocrit and resulting tissue hypoxia. Often the total bilirubin levels are high in patients with SCD because the hemoglobin released from damaged and dead red blood cells is broken down into iron and heme molecules. The heme molecules then are metabolized into free bilirubin.

The total white blood cell (WBC) count is usually high in patients with SCD. This elevation is related to chronic inflammation caused by tissue hypoxia and ischemia.

Imaging Assessment

Bone changes occur as a result of chronically stimulated marrow and low bone oxygen levels. The skull may show changes on x-ray as a result of bone surface cell destruction and new growth, giving the skull a “crew cut” appearance on x-ray. X-rays of joints may show necrosis and destruction. Ultrasonography, computed tomography (CT), positron

emission tomography (PET), and magnetic resonance imaging (MRI) may show soft-tissue and organ changes from poor oxygenation and chronic inflammation.

Other Diagnostic Assessment

Electrocardiographic (ECG) changes document cardiac infarcts and tissue damage. Specific ECG changes are related to the area of the heart that has been damaged. Echocardiograms may show cardiomyopathy and decreased cardiac output (low ejection fraction).

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which laboratory value in a client with sickle cell disease does the nurse report immediately to the health care provider?

- A. Hematocrit 24%
- B. Hemoglobin S (HbS) 78%
- C. Platelet count 260,000/mm³
- D. White blood cell (WBC) count 20,000/mm³

ANALYSIS

The priority problems for the patient with sickle cell disease are:

1. Acute Pain related to poor tissue oxygenation
2. Chronic Pain related to joint destruction
3. Potential for sepsis
4. Potential for multiple organ dysfunction and death

INTERVENTIONS

Managing Pain

The most common problem of SCD is pain (Granados & Jacob, 2009). The pain with sickle cell crisis is the result of tissue injury caused by poor oxygenation from obstructed blood flow. At times, patients have mild pain episodes that can be managed at home. However, pain is often severe enough to require hospitalization and large doses of opioid analgesics. Acute pain episodes have a sudden onset, usually involving the chest, back, abdomen, and extremities. Complications of SCD, such as bone necrosis, can cause severe, chronic pain, requiring large doses of opioid analgesics.

Ask the patient whether the pain is typical of past pain episodes. If not, other pain causes or disease complications must be explored. Use of a pain rating scale can help proper pain management. Ask the patient to rate pain on a scale ranging from 0 to 10, and evaluate the effectiveness of interventions based on the ratings.

Concerns about substance abuse can lead to inadequate pain treatment in these patients. Opioid addiction is rare, occurring in only 2% to 5% of patients with SCD. Pain management is based on past pain history, previous drug use, disease complications, and current pain assessment. Health care providers need to be aware of their own attitudes when caring for this population. If substance abuse is suspected, management of addiction is incorporated into the patient’s overall treatment plan. Management of substance abuse and SCD poses many challenges, because the patient usually cannot be expected to be totally opioid-free. Addicted patients with acute pain crisis may need opioids for short periods.

CHART 42-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient in Sick Cell Crisis

- Administer oxygen.
- Administer prescribed pain medication.
- Hydrate the patient with normal saline IV and with beverages of choice (without caffeine) orally.
- Remove any constrictive clothing.
- Encourage the patient to keep extremities extended to promote venous return.
- Do not raise the knee position of the bed.
- Elevate the head of the bed no more than 30 degrees.
- Keep room temperature at or above 72° F (22.2° C).
- Avoid taking blood pressure with external cuff.
- Check circulation in extremities every hour:
 - Pulse oximetry of fingers and toes
 - Capillary refill
 - Peripheral pulses
 - Toe temperature

Drug therapy for patients in acute sickle cell crisis often starts with at least 48 hours of IV analgesics. (Chart 42-2 lists best practices for nursing care of the patient in sickle cell crisis.) Morphine and hydromorphone (Dilaudid) are given IV on a routine schedule or by infusion pump using patient-controlled analgesia (PCA) (see Chapter 5). Once relief is obtained, the IV dose can be tapered and the drug given orally. Avoid “as needed” (PRN) schedules because they do not provide adequate relief. Avoid IM injections because absorption is impaired by poor perfusion and sclerosed skin. Moderate pain may be treated with oral opioids or NSAIDs. (See Chapter 5 for more information on pain management.)

Hydroxyurea (Droxia) has been successfully used to reduce the number of sickling and pain episodes (Pack-Mabien & Haynes, 2009). Hydroxyurea works by stimulating fetal hemoglobin (HbF) production. HbF is present during fetal development, but its production is turned off before birth. Increasing the level of HbF reduces sickling of red blood cells in patients with sickle cell disease. However, this drug is associated with an increased incidence of leukemia. Long-term complications should be discussed with the patient before this therapy is started. Hydroxyurea also suppresses bone marrow function, and regular follow-up to monitor complete blood counts (CBCs) for drug toxicity is important. *Hydroxyurea also causes birth defects and should not be taken by anyone who is pregnant or likely to become pregnant.*

! NURSING SAFETY PRIORITY

Action Alert

Teach sexually active women of childbearing age to use at least two methods of birth control while taking hydroxyurea and for 1 month after the drug is discontinued because this drug can cause severe birth defects.

Hydration by the oral or IV route helps reduce the duration of pain episodes. Urge the patient to drink water or juices. Hypotonic fluids, such as dextrose 5% in water (D₅W) or dextrose 5% in 0.45% sodium chloride, are usually infused at 250 mL/hr for 4 hours. Hypotonic fluids are used because

the patient's blood volume is usually hypertonic as a result of dehydration. Using hypotonic fluids can help bring the patient's blood osmolarity back down to the normal range of 270 to 300 mOsm. The IV rate is then reduced to 125 mL/hr if more hydration is needed.

Complementary therapies and other measures, such as keeping the room warm, using distraction and relaxation techniques, positioning with support for painful areas, aroma therapy, therapeutic touch, and warm soaks or compresses, all help reduce pain perception.

! NURSING SAFETY PRIORITY

Action Alert

Do not assume that complementary therapies alone will provide adequate pain relief. Analgesics are needed to manage sickle cell pain.

Preventing Sepsis

The patient with SCD is at greater risk for bacterial infection because of decreased spleen function resulting from anoxic damage to the spleen. Over time, the spleen may become completely nonfunctional. Expected outcomes of interventions include preventing infection, controlling infection, and starting treatment early for specific infections. The patient who develops a fever should have diagnostic testing for sepsis including CBC with differential, blood cultures, reticulocyte count, urine culture, and a chest x-ray. Usually these patients are started on prophylactic antibiotics.

Prevention and early detection strategies are used to protect the patient in sickle cell crisis from infection. Frequent, thorough handwashing is of the utmost importance. Any person with an upper respiratory tract infection who must enter the patient's room wears a mask. Use strict aseptic technique for all invasive procedures. Coordinate with all members of the health care team to ensure adherence to these strategies.

Continually assess the patient for infection, and monitor the daily CBC with differential WBC count. Inspect the mouth every 8 hours for lesions indicating fungal or viral infection. Listen to the lungs every 8 hours for crackles, wheezes, or reduced breath sounds. Each time the patient voids, inspect the urine for odor and cloudiness, and ask about urgency, burning, or pain during urination. Take vital signs at least every 4 hours to assess for fever, or supervise this action when performed by others.

Drug therapy is a major defense against the infections that develop in the patient with SCD. Prophylactic therapy with twice-daily oral penicillin reduces the number of pneumonia and other streptococcal infections. Urge the patient to receive yearly influenza vaccinations and to receive the pneumonia vaccine. Drug therapy for an actual infection can control infection and prevent sepsis. Drugs used depend on the sensitivity of the specific organism causing the infection, as well as on the extent of the infection.

Preventing Multiple Organ Dysfunction

Continued blood vessel occlusion by clumping of sickled cells increases the risk for multiple organ dysfunctions. Acute chest syndrome, in which a vaso-occlusive episode (VOE) causes infiltration and damage to the pulmonary system, is a major cause of death in adults with SCD (Hernandez &

Patterson, 2009). Preventing dysfunction of any organ is important in SCD management; however, preventing heart and lung damage is a priority. Management of SCD focuses on prevention of VOs and *promotion of oxygenation*.

The patient in sickle cell crisis is admitted to the acute care hospital. Assess for *adequate perfusion* to all body areas. Remove restrictive clothing, and instruct the patient to avoid flexing the knees and hips.

Hydration is needed because dehydration increases cell sickling and must be avoided. Assist him or her in maintaining adequate hydration. The patient in acute crisis needs an oral or IV fluid intake of at least 200 mL/hr.

Oxygen is given during crises because lack of oxygen is the main cause of sickling. Ensure that oxygen therapy is nebulized to prevent dehydration. Monitor oxygen saturation using pulse oximetry. Patients with low oxygen saturation should have an arterial blood gas (ABG) drawn and a chest x-ray.

Transfusion with RBCs can be helpful to increase HbA levels and dilute HbS levels. During transfusion, monitor the patient for complications of the procedure (discussed on pp. 900-901 in the [Transfusion Reactions](#) section).

Transfusions are prescribed cautiously to prevent iron overload from repeated transfusions. Iron overload damages the heart, liver, and endocrine organs. Monitor the patient's serum ferritin, serum iron (Fe), and total iron-binding capacity (TIBC). Deferoxamine mesylate (Desferal, Desferrioxamine) or deferasirox (Exjade) may be prescribed to manage transfusion-induced iron overload.

In some treatment centers, hematopoietic stem cell transplantation (HSCT) is performed to correct abnormal hemoglobin permanently. Because HSCT is expensive and may result in life-threatening complications, its risks and benefits need to be considered for each patient.

DECISION-MAKING CHALLENGE

Safety; Patient-Centered Care

A 23-year-old African-American woman who has a history of sickle cell disease is brought to the emergency department. She reports joint and back pain that is becoming worse rapidly. She rates her pain as a 9 on a 0-to-10 scale. She is pale, and her vital signs are normal except for a temperature of 101.5° F (38.6° C). She tells you that she had sexual intercourse for the first time 2 days ago. She also says that she now has pain just above the pubic bone during and after urination and that the urine burns.

1. What questions related to pain would you ask this patient?
2. What drug or drugs for pain would you expect this patient to receive and by which route?
3. What diagnostic tests would you expect to be requested for this patient?
4. What nursing assessments would be most important for you to make at this time?
5. What factor or factors could have triggered this crisis episode?

Community-Based Care

Sickle cell disease (SCD) becomes worse over time. Rarely is there a true remission, although the number of crisis episodes may be reduced. Care focuses on teaching the patient and family how to prevent crises and complications ([Chart 42-3](#)). The patient with SCD may receive care in acute care, subacute care, extended or assistive care, and home care settings.

CHART 42-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Sickle Cell Crisis

- Drink at least 3 to 4 liters of liquids every day.
- Avoid alcoholic beverages.
- Avoid smoking cigarettes or using tobacco in any form.
- Contact your health care provider at the first sign of illness or infection.
- Be sure to get a "flu shot" every year.
- Ask your health care provider about taking the pneumonia vaccine.
- Avoid temperature extremes of hot or cold.
- Be sure to wear socks and gloves when going outside on cold days.
- Avoid planes with unpressurized passenger cabins.
- Avoid travel to high altitudes (e.g., cities like Denver and Santa Fe).
- Ensure that any health care professional who takes care of you knows you have sickle cell disease, especially the anesthesia provider and radiologist.
- Consider genetic counseling.
- Avoid strenuous physical activities.
- Engage in mild, low-impact exercise at least three times a week when you are not in crisis.

Teach the patient to avoid specific activities that lead to hypoxia and hypoxemia. Stress the recognition of the early symptoms of crisis so that interventions can be started early to prevent pain, complications, and permanent tissue damage. He or she is often given opioid analgesics for self-management of sickle cell crises at home. Teach the patient and family about the correct use of these drugs. In addition, counsel patients about the hereditary aspects of SCD and provide information about prenatal diagnosis, birth control methods, and pregnancy options.

WOMEN'S HEALTH CONSIDERATIONS

Pregnancy in women with SCD may be life threatening. Patients who have damage to vital organs are advised against becoming pregnant. Usually, barrier methods of contraception (cervical cap, diaphragm, or condoms with or without spermicides) are recommended for women with SCD. The use of oral contraceptives (OCs) is controversial, because OCs may increase clot formation, especially among smokers, predisposing them to crises. The risks versus benefits of OCs must be evaluated for each patient.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A woman whose hemoglobin S levels are less than 1% has a brother with sickle cell disease (SCD) and both parents have been diagnosed as carriers for the disorder. She asks what her risks are of having a child with sickle cell disease. What is the nurse's best response?

- A. "Because you do not have the trait, you cannot have a child with SCD regardless of your partner's sickle cell status."
- B. "Because both your parents have the trait, it is possible for you to have a child with SCD if your partner actually has the disease."
- C. "Because your brother actually has SCD, the risk for your children having SCD is 50% with each pregnancy."
- D. "Because you are a woman, your daughters will each have a 50% risk for having the disease, and all of your sons will be carriers of the trait."

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY ANEMIA

Pathophysiology

Many forms of **hemolytic** (blood cell–destroying) anemia are present from birth as a result of defects or deficiencies of one or more enzymes in red blood cells (RBCs). More than 200 such disorders are known. Most of these enzymes are needed to complete some critical step in RBC energy production. The most common type of inherited hemolytic anemia is the deficiency of the enzyme *glucose-6-phosphate dehydrogenase* (G6PD). This disease is inherited as an X-linked recessive disorder, most fully expressed in homozygous males, although partial expression (carrier state) is possible in heterozygous females. This type of anemia affects about 10% of all African Americans and also may occur in Sephardic Jews, Greeks, Iranians, Chinese, Filipinos, and Indonesians, with a frequency ranging from 5% to 40% (McCance et al., 2010).

G6PD stimulates reactions in glucose metabolism. Because RBCs contain no **mitochondria** (sites of production of adenosine triphosphate [ATP]), metabolism of glucose is required to generate energy in these cells. Newly produced RBCs from patients with G6PD deficiency have sufficient levels of G6PD. Cells with reduced amounts of G6PD break more easily during exposure to some drugs (e.g., sulfonamides, aspirin, quinine derivatives, rasburicase, chloramphenicol, dapsone, high doses of vitamin C, and thiazide diuretics) and exposure to benzene and other toxins.

The patient usually does not have symptoms until exposed to these agents or until a severe infection develops. After exposure to any of these agents, patients have acute breakage of RBCs lasting from 7 to 12 days. During this acute phase, anemia and jaundice develop. The hemolytic reaction is limited because only older RBCs, containing less G6PD, are destroyed.

PATIENT-CENTERED COLLABORATIVE CARE

Prevention is the most important therapeutic measure. Men who belong to the high-risk groups should be tested for this problem before being given drugs that can cause the hemolytic reaction. Screening test results are based on discoloration of methylene blue and reduction of methemoglobin. Donated blood is screened for this deficiency before transfusion because cells deficient in G6PD can be hazardous for the recipient.

Hydration is important during an episode of hemolysis to prevent debris and hemoglobin from collecting in the kidney tubules, which can lead to acute kidney failure. Osmotic diuretics, such as mannitol (Osmitol), may help prevent this complication. Transfusions are needed when anemia is present and kidney function is normal (see **Transfusion Therapy** section on pp. 897-901).

IMMUNOHEMOLYTIC ANEMIA

The most common types of hemolytic anemias in North America are the immunohemolytic anemias, also referred to as *autoimmune hemolytic anemias* (McCance et al., 2010). The pathophysiology of hemolytic anemias involves the excessive destruction of red blood cells followed by acceleration of erythropoiesis. Acquired hemolytic syndromes result

from increased RBC destruction occurring in response to trauma, viral infection, malarial infection, exposure to certain chemicals or drugs, and autoimmune reactions. All increase the rate of RBC destruction by causing membrane **lysis** (breakage).

In immunohemolytic anemia, immune system products (e.g., antibodies) attack a person's own RBCs for unknown reasons. Some hemolytic anemias occur with other autoimmune disorders (e.g., systemic lupus erythematosus) or other conditions such as lymphoma, leukemia, and other neoplastic disorders (Coyer & Lash, 2008). Regardless of the cause, RBCs are viewed as non-self by the immune system and then are attacked and destroyed.

The two types of immunohemolytic anemia are warm antibody anemia and cold antibody anemia. **Warm antibody anemia** occurs with immunoglobulin G (IgG) antibody excess. These antibodies are most active at 98.6° F (37° C) and may be triggered by drugs, chemicals, or other autoimmune problems. **Cold antibody anemia** has complement protein fixation on immunoglobulin M (IgM) and occurs most at 86° F (30° C). This problem often occurs with a Raynaud's-like response in which the arteries in the hands and feet constrict profoundly in response to cold temperatures or stress.

Management depends on symptom severity. Steroid therapy to suppress immune function is the first line of treatment and is temporarily effective in most patients. Splenectomy and more intense immunosuppressive therapy with cancer chemotherapy drugs may be used if steroid therapy fails. Plasma exchange therapy to remove attacking antibodies is effective for patients who do not respond to immunosuppressive therapy.

ANEMIAS RESULTING FROM DECREASED PRODUCTION OF RED BLOOD CELLS

Anemias caused by decreased RBC production occur in response to many problems. Some are caused by failure of the bone marrow to produce healthy RBCs. Anemias also are caused by failure of the body to make or absorb a substance needed for RBC production.

CONSIDERATIONS FOR OLDER ADULTS

Older patients often have restricted diets and may be unable to eat meat because of tooth loss or economic reasons and thus are at risk for iron deficiency anemia. Ask about a family history of anemia. B₁₂ deficiency anemia often occurs in patients 50 to 80 years of age and may result from an inherited genetic mutation.

IRON DEFICIENCY ANEMIA

Adults usually have between 2 and 6 g of iron, depending on the size of the person and the amount of hemoglobin in the cells. About two thirds of this iron is contained in hemoglobin. The other one third is stored in the bone marrow, spleen, liver, and muscle. With iron deficiency, the iron stores are depleted first, followed by the hemoglobin stores. As a result, RBCs are small (**microcytic**) and the patient has mild symptoms of anemia, including weakness and pallor. Other clinical manifestations include fatigue, reduced exercise tolerance, and fissures at the corners of the mouth. Nails become brittle, thin, coarsely ridged, or spoon-shaped and concave (Coyer &

Lash, 2008). In iron deficiency anemia, serum ferritin values are less than 10 ng/mL (normal range is 12 to 300 ng/mL).

Iron deficiency anemia is the most common anemia worldwide, especially among women, older adults, and people with poor diets. It can result from blood loss, poor GI absorption of iron, and an inadequate diet (Simmons, 2010). The problem is a decreased iron supply for the developing RBC.

Any adult with iron deficiency should be evaluated for abnormal bleeding, especially from the GI tract. Management of iron deficiency anemia involves increasing the oral intake of iron from food sources (e.g., red meat, organ meat, egg yolks, kidney beans, leafy green vegetables, and raisins). An adequate diet supplies about 10 to 15 mg of iron per day. However, only 5% to 10% of dietary iron is absorbed. This amount is enough to meet the needs of men and of women after childbearing age but is not sufficient to supply the greater needs of menstruating women. If iron losses are mild, oral iron supplements, such as ferrous sulfate, are started. This treatment should cause the hemoglobin level to rise about 2 g/dL in 4 weeks. Treatment continues until the hemoglobin level returns to normal. Instruct patients to take the iron supplement between meals for better absorption and to reduce GI distress. When iron deficiency anemia is severe, iron solutions can be given IV or IM. When given IM, these solutions must be given using the Z-track best practice method outlined in Chart 42-4. There is controversy as to whether the dorsal gluteal site or the ventrogluteal site should be used for iron dextran (Dexferrum) therapy. Although the ventrogluteal site is recommended as best practice for most IM injections, including those administered by Z-track (Zimmermann, 2010), the drug manufacturer continues to recommend the dorsal gluteal site (MD Consult, 2010). A

CHART 42-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Administering Iron Dextran by the Z-Track Method

- Draw the drug up into the syringe using aseptic technique.
- Add 0.25 mL of air to the syringe.
- Discard the needle used to draw up the drug.
- Place a new needle (22-gauge, 2 to 3 inches long) on the syringe.
- Make certain that the injection site is in bright light.
- Select the dorsal gluteal site (drug manufacturer's recommendation).
- Identify appropriate landmarks for administration into the upper, outer quadrant.
- Once the site is selected, pull the skin and subcutaneous tissues sideways away from the muscle.
- Clean the site while holding the skin and subcutaneous tissues off to the side.
- Insert the needle deeply into the muscle tissue.
- Aspirate to determine needle placement.
- Iron dextran is black; look very closely to determine whether blood is being aspirated into the syringe.
- If blood is aspirated, withdraw the needle and begin the procedure again from the first step.
- If no blood is aspirated, inject the drug slowly, followed by injection of the air bubble.
- Quickly withdraw the needle.
- Release the skin and subcutaneous tissue.
- Do not massage the injection site.

new IV drug for iron deficiency anemia associated with chronic kidney disease is ferumoxytol (Feraheme). It has the advantage of being administered at higher dosages over a shorter period of time compared with other IV iron preparations (Belavic, 2010).

VITAMIN B₁₂ DEFICIENCY ANEMIA

Production of RBCs depends on adequate DNA synthesis in the precursor cells so that cell division and growth into functional RBCs can occur. All cell division requires adequate amounts of folic acid to make DNA. One function of vitamin B₁₂ is to activate the enzymes that move folic acid into the cell where DNA synthesis occurs. Vitamin B₁₂ deficiency causes anemia by inhibiting folic acid transport and reducing DNA synthesis in precursor cells. These precursor cells then undergo improper DNA synthesis and increase in size. Only a few are released from the bone marrow. This type of anemia is called *megaloblastic* or **macrocytic anemia** because of the large size of these abnormal cells.

Vitamin B₁₂ deficiency results from poor intake of foods containing vitamin B₁₂. This more often occurs with vegetarian diets or diets lacking dairy products. Problems such as small bowel resection, chronic diarrhea, diverticula, tapeworm, or overgrowth of intestinal bacteria can lead to poor absorption of vitamin B₁₂. Anemia resulting from failure to absorb vitamin B₁₂ (**pernicious anemia**) is caused by a deficiency of **intrinsic factor** (a substance normally secreted by the gastric mucosa), which is needed for intestinal absorption of vitamin B₁₂.

Vitamin B₁₂ deficiency anemia may be mild or severe, usually develops slowly, and produces few symptoms. Patients usually have pallor and jaundice, as well as **glossitis** (a smooth, beefy-red tongue) (Fig. 42-3), fatigue, and weight loss. Because vitamin B₁₂ is needed for normal nerve function, patients with pernicious anemia may also have **paresthesias** (abnormal sensations) in the feet and hands and poor balance (Nettina, 2009).

When anemia is caused by a dietary deficiency, the focus of management is to increase the intake of foods rich in vitamin B₁₂ (animal proteins, eggs, and dairy products). Vitamin supplements may be prescribed when anemia is severe. Vitamin B₁₂ and folic acid levels are monitored. Patients who may have pernicious anemia are tested using the

FIG. 42-3 Glossitis, a smooth tongue as a result of vitamin B₁₂ deficiency anemia.

Shilling test, which measures the presence of vitamin B₁₂ in the urine after the patient is given an oral dose of radioactive vitamin B₁₂. If the patient does not absorb the radioactive vitamin B₁₂ because of pernicious anemia, it cannot get into the urine. Patients who have pernicious anemia are given vitamin B₁₂ injections weekly at first, then monthly for the rest of their lives. A new formulation of the drug *cyanocobalamin* (CaloMist) that delivers vitamin B₁₂ by nasal spray also is available to maintain vitamin levels after the patient's deficiency has first been corrected by the traditional injection method.

FOLIC ACID DEFICIENCY ANEMIA

Folic acid deficiency can also cause anemia. Manifestations are similar to those of vitamin B₁₂ deficiency, but nervous system functions remain normal because folic acid deficiency does not affect nerve function. The absence of neurologic problems helps distinguish folic acid deficiency from vitamin B₁₂ deficiency. The disease develops slowly, and symptoms may be attributed to other problems or diseases.

Three causes of folic acid deficiency are poor nutrition, malabsorption, and drugs. Poor nutrition, especially a diet lacking green leafy vegetables, liver, yeast, dried beans, and nuts, is the most common cause. Malabsorption syndromes, such as Crohn's disease, are the second most common cause. Chronic alcohol abuse with malnutrition is another cause. Anticonvulsants and oral contraceptives can slow or prevent the absorption and conversion of folic acid to its active form, leading to folic acid deficiency and anemia.

Prevention begins by identifying high-risk patients, such as older, debilitated patients with alcoholism; patients at risk for malnutrition; and those with increased folic acid requirements. A diet rich in foods containing folic acid and vitamin B₁₂ prevents a deficiency. By assessing dietary habits for all patients, you can determine which patients are at risk for diet-induced anemias. This type of anemia is managed with scheduled folic acid replacement therapy.

APLASTIC ANEMIA

Pathophysiology

Aplastic anemia is a deficiency of circulating red blood cells (RBCs) because of failure of the bone marrow to produce these cells. It is caused by an injury to the immature precursor cell for red blood cells, known as the **pluripotent stem cell**. Although aplastic anemia sometimes occurs alone, it usually occurs with **leukopenia** (a reduction in white blood cells [WBCs]) and **thrombocytopenia** (a reduction in platelets). These three problems occur together because the damaged bone marrow loses the ability to produce any of these cells. **Pancytopenia** (a deficiency of all three cell types) is common in aplastic anemia. Disease onset may be slow or rapid.

The most common type of the disease is acquired aplastic anemia. It can be caused by long-term exposure to toxic agents, drugs (see Table 41-3 in Chapter 41), ionizing radiation, or infection. In about 50% of cases, the cause of aplastic anemia is unknown. The disease may follow viral infection, but it is not known exactly how the bone marrow is damaged. The most common hereditary form of the disease is Fanconi's anemia.

PATIENT-CENTERED COLLABORATIVE CARE

Assess for symptoms of bone marrow failure and *poor oxygenation* such as weakness, pallor, and petechiae or ecchymosis. A complete blood count (CBC) shows severe macrocytic anemia, leukopenia and thrombocytopenia. A bone marrow biopsy may show replacement of cell-forming marrow with fat. Infection is common with leukopenia, especially neutropenia.

Blood transfusions are used only when the anemia causes disability or when bleeding is life threatening because of low platelet counts. Unnecessary transfusion increases the chances for developing immune reactions to platelets and shortens the life span of the transfused cell. This therapy is discontinued as soon as the bone marrow begins to produce RBCs.

Allogeneic hematopoietic stem cell transplantation (transplantation of bone marrow or stem cells from a sibling or matched unrelated donor) remains the preferred and most successful method of treatment for aplastic anemia that does not respond to other therapies. Cost, availability, and complications limit this treatment in aplastic anemia. For those patients who are unable to undergo such treatment or lack a suitable donor, immunosuppressive therapy remains the treatment of choice (Afable & Lyon, 2008).

Immunosuppressive therapy helps patients who have the types of aplastic anemia with a disease course similar to that of autoimmune problems. Drugs such as prednisone, antithymocyte globulin (ATG), and cyclosporine A (Sandimmune) have resulted in partial or complete remissions. The combination of ATG and cyclosporine A has been found to improve results (Afable & Lyon, 2008). Another immunosuppressant agent that has been found to improve both blood counts and transfusion requirements in patients with moderate aplastic anemia is daclizumab (Zenapax). *Splenectomy* (removal of the spleen) may be needed for patients with an enlarged spleen that is either destroying normal RBCs or suppressing their development.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement made by a client with folic acid deficiency anemia indicates to the nurse a correct understanding of self-management for this health problem?

- A. "If my fingers and toes become numb, I will notify my health care provider immediately."
- B. "I will stop playing contact sports or any activity that increases my risk for injury."
- C. "My diet now includes more carrots, cauliflower, and apples."
- D. "I have stopped drinking alcohol completely."

POLYCYTHEMIA

In polycythemia, the number of red blood cells (RBCs) in the blood is *greater* than normal. The blood of a patient with polycythemia is **hyperviscous** (thicker than normal blood). The problem may be temporary (occurring as a result of other conditions) or chronic. One type of polycythemia, polycythemia vera (PV), is fatal if left untreated.

POLYCYTHEMIA VERA

Pathophysiology

Polycythemia vera (PV) is a disease with a sustained increase in blood hemoglobin levels to 18 g/dL, an RBC count of 6 million/mm³, or a hematocrit of 55% or greater. PV is a cancer of the RBCs with three major hallmarks: massive production of RBCs, excessive leukocyte production, and excessive production of platelets. Extreme **hypercellularity** (cell excess) of the peripheral blood occurs in people with PV.

The patient's facial skin and mucous membranes have a dark, flushed (**plethoric**) appearance. These areas appear purplish or cyanotic because the blood in these tissues is poorly oxygenated. Most patients have intense itching caused by dilated blood vessels and *poor tissue oxygenation*. Blood viscosity is increased, resulting in hypertension. Superficial veins are visibly distended. The thick blood moves more slowly through all tissues and places increased demands on the heart, resulting in hypertension. In some highly vascular areas, blood flow may become so slow that stasis occurs. Vascular stasis causes **thrombosis** (clot formation) within the smaller vessels, occluding blood vessels. The blood vessel occlusion leads to tissue hypoxia, anoxia and, later, to infarction and necrosis. Tissues most at risk for this problem are the heart, spleen, and kidneys, although infarction and damage can occur in any organ or tissue.

Because the actual number of cells in the blood is greatly increased and the cells are not completely normal, cell life spans are shorter. The shorter life spans and increased cell production cause a rapid turnover of circulating blood cells. This rapid turnover increases the amount of cell debris (released when cells die) in the blood, adding to the general "sludging" of the blood. This debris includes uric acid and potassium, which cause the symptoms of gout and **hyperkalemia** (elevated serum potassium level).

Other manifestations of PV are related to abnormal RBCs. Even though the number of RBCs is greatly increased, their oxygen-carrying capacity is impaired, and patients have *poor oxygenation* with severe hypoxia. Patients with PV also have bleeding problems because of platelet impairment.

PATIENT-CENTERED COLLABORATIVE CARE

Polycythemia vera is a malignant disease that progresses in severity over time. If left untreated, few people with PV live longer than 2 years after diagnosis. With management by repeated pheresis (two to five times per week), the patient may live 10 to 15 years or longer. (**Pheresis** is the withdrawal of whole blood and removal of the patient's RBCs to decrease the number of RBCs and reduce blood viscosity. The remaining plasma is then re-infused back into the patient.) Increasing hydration and promoting venous return help prevent clot formation. The purpose of therapy is to prevent clot formation and includes the use of anticoagulants. **Chart 42-5** lists health tips for patients with PV.

As the disease progresses, drug therapy is used to control it, although aggressive IV chemotherapy is no longer recommended because of its increased risk for inducing

CHART 42-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Polycythemia Vera

- Drink at least 3 liters of liquids each day.
- Avoid tight or constrictive clothing, especially garters and girdles.
- Wear gloves when outdoors in temperatures lower than 50° F (10° C).
- Keep all health care–related appointments.
- Contact your physician at the first sign of infection.
- Take anticoagulants as prescribed.
- Wear support hose or stockings while you are awake and up.
- Elevate your feet whenever you are seated.
- Exercise slowly and only on the advice of your physician.
- Stop activity at the first sign of chest pain.
- Use an electric shaver.
- Use a soft-bristled toothbrush to brush your teeth.
- Do not floss between your teeth.

leukemia. Aspirin therapy may be used to decrease clot formation. However, the benefits must be weighed against the increased risk for GI bleeding associated with this therapy. Hydroxyurea, an oral chemotherapy drug, may be prescribed for severe manifestations of the disease.

MYELOYDYSPLASTIC SYNDROMES

Pathophysiology

Myelodysplastic syndromes (MDSs) are a group of disorders caused by the formation of abnormal bone marrow cells. These abnormal cells are usually destroyed shortly after they are released into the blood. As a result, patients with MDS have a decrease in all blood cell types. Anemia is a common problem, occurring in 90% of patients with MDS, although **neutropenia** (low white blood cell [WBC]) count and **thrombocytopenia** (low platelets) are also often present.

Although MDS can occur at any age, it is most common in people age 60 years or older. MDS is not officially a type of cancer but does have cancer-like features and is considered to be a *precancerous* state. Like cancer, MDS arises from a single population of abnormal cells. About 30% of all patients with MDS do eventually develop acute leukemia (Kumar, Abbas, Fausto, & Aster, 2010). A number of subtypes of MDS have different prognoses and responses to therapy. Patients are categorized into risk groups (i.e., low, intermediate [1 and 2], high) based on the severity of **pancytopenia** (low counts of all blood cell types), cytogenetic abnormalities, and numbers of blast cells (immature WBC cells) found in the bone marrow (Kurtin & Demakos, 2010).

The exact cause of MDS is not clear. Risk factors include normal physiologic changes associated with aging, chemical exposures (pesticides, benzene), tobacco smoke, and exposure to radiation or chemotherapy drugs. Diagnosis is made by examination of the chromosomes and the genes within the chromosomes (*cytogenetic testing*) of the bone marrow cells. Peripheral blood smears are used to assess the level of cell maturation and the proportion of abnormal cells.

PATIENT-CENTERED COLLABORATIVE CARE

The only curative treatment for MDS is an allogeneic hematopoietic stem cell transplantation, which is often not an option because of the advanced age of the patient (Kurtin & Demakos, 2010). For low-risk and intermediate-1-risk MDS, the antitumor immunomodulatory agent *lenalidomide* (Revlimid) is approved for patients whose dysplastic cells have the chromosome abnormality of a deleted 5q. Two other agents that are approved for intermediate-2-risk and high-risk MDS are hypomethylating agents *azacitidine* (Vidaza) and *decitabine* (Dacogen). The results of clinical trials have increased the understanding of these treatments alone or in combination with other therapies. Effective management often requires at least 3 to 6 months to achieve a clinical response; therefore supportive care is necessary.

Supportive care includes blood transfusions for anemia and platelet transfusions when platelet levels are very low. Erythropoietin stimulating proteins, such as epoetin alfa (Epogen, Procrit) or darbepoetin alfa (Aranesp) may be given in addition to transfusions. Frequent transfusions can lead to iron overload and organ damage.

Chelating therapy may be needed to reduce the iron overload before damage to the liver and heart occurs. **Chelating** is the chemical binding of iron and its removal from the body. It is indicated for patients who receive more than 20 units of red blood cell transfusions or for those whose serum ferritin levels are greater than 2500 mcg/L. Chelating drugs include deferasirox (Exjade) and deferoxamine mesylate (Desferal, Desferrioxamine).

WHITE BLOOD CELL DISORDERS

As discussed in Chapter 19, white blood cells (WBCs), or **leukocytes**, provide protection from infection and cancer development. This protection depends on maintaining normal numbers and ratios of the different mature, circulating WBCs. When any one type of WBC is present in either abnormally high or abnormally low amounts, immune function is altered to some degree, as are oxygen transport and blood clotting, placing patients at risk for many complications. This section covers the changes and nursing care for patients with disorders involving overgrowth of specific types of WBCs. (See Chapter 21 for the problems and care needs for patients with immune deficiency.)

LEUKEMIA

Pathophysiology

Leukemia is a type of cancer with uncontrolled production of immature WBCs (usually “blast” cells) in the bone marrow. As a result, the bone marrow becomes overcrowded with immature, nonfunctional cells and production of normal blood cells is greatly decreased. Leukemia may be **acute**, with a sudden onset and short duration, or **chronic**, with a slow onset and symptoms that persist for years.

Leukemias are classified by cell type. Leukemic cells coming from the lymphoid pathways (see Fig. 19-3 in Chapter 19) are typed as **lymphocytic** or **lymphoblastic**. Leukemias in which the abnormal cells come from the myeloid pathways

are typed as **myelocytic** or **myelogenous**. Several subtypes exist for each of these diseases, which are classified according to the degree of maturity of the abnormal cell and the specific cell type involved. *Biphenotypic leukemia* is acute leukemia that shows both lymphocytic and myelocytic features.

With leukemia, cancer most often occurs in the stem cells or early precursor leukocyte cells, causing excessive growth of a specific type of immature leukocyte. In some chronic leukemias, the cancerous cells may be more mature. These cells are abnormal, and their excessive production in the bone marrow stops normal bone marrow production of RBCs, platelets, and mature leukocytes. Anemia, thrombocytopenia, and leukopenia result. Often the number of immature, abnormal WBCs (called “blasts”) in the blood is greatly elevated, and these cells cannot provide infection protection. Leukemic cells can also be found in the spleen, liver, lymph nodes, and central nervous system. Without treatment, the patient will die of infection or hemorrhage. For patients with acute leukemia, these changes occur rapidly and, without intervention, progress to death. Chronic leukemia may be present for years before changes appear.

Etiology and Genetic Risk

The exact cause of leukemia is unknown, although many genetic and environmental factors are involved in its development. The basic problem involves damage to genes controlling cell growth. This damage then changes cells from a normal to a **malignant** (cancer) state. Analysis of the bone marrow of a patient with acute leukemia shows abnormal chromosomes about 50% of the time (McCance et al., 2010). Possible risk factors for the development of leukemia include ionizing radiation, viral infection, exposure to chemicals and drugs, bone marrow **hypoplasia** (reduced production of blood cells), genetic factors, immunologic factors, environmental factors, and the interaction of these factors.

Ionizing radiation exposures such as radiation therapy for cancer treatment or heavy radiation exposure (e.g., the atomic bomb at Hiroshima or the nuclear accident at Chernobyl) increase the risk for leukemia development, particularly acute myelogenous leukemia (AML).

Chemicals and drugs have been linked to leukemia development because of their ability to damage DNA. Previous treatment for cancer with chemotherapy (e.g., melphalan, doxorubicin, etoposide, and cyclophosphamide) poses risks for leukemia development about 5 to 8 years after treatment. Table 41-3 in Chapter 41 lists chemicals and drugs that damage the hematologic system.

Bone marrow hypoplasia can increase leukemia risk by reducing or changing the rate of bone marrow cell production. Disorders that have marrow hypoplasia and may lead to leukemia development include Fanconi’s anemia and myelodysplastic syndromes.

Genetic factors influence leukemia development. There is an increased incidence of the disease among patients with hereditary conditions such as Down syndrome, Bloom syndrome, Klinefelter syndrome, and Fanconi’s anemia. Identical siblings of patients with leukemia have a higher incidence of leukemia than do the general population.

Immunologic factors, especially immune deficiencies, may promote the development of leukemia. Leukemia related to immune deficiency may be a result of loss of immune

protection, or the same mechanisms that cause the immune deficiency may also trigger cancer in the WBCs.

Interaction of many host and environmental factors may result in leukemia. Because each person tolerates the interaction of these factors differently, it is difficult to determine the origin of any specific leukemia.

Incidence/Prevalence

Leukemia accounts for 2% of all new cases of cancer and 4% of all deaths from cancer (American Cancer Society, 2011). The incidence depends on many factors, including the type of WBC affected, age, gender, race, and geographic locale.

In the United States, about 44,000 new cases of leukemia occur each year (American Cancer Society, 2011). Leukemia is classified into any one of four types based on the cell type affected and how fast the disease progresses:

- *Acute myelogenous leukemia (AML)* is the most common form of adult-onset acute leukemia. There are eight subtypes of AML, which are diagnosed and classified on the basis of the number of healthy blood cells, the number of leukemic cells, and the specific chromosomal abnormalities identified in the leukemic cells. Disease prognosis varies by subtype and chromosomal abnormality. *Acute promyelocytic leukemia (APL)* is a common subtype of adult-onset AML that is now the most curable of the adult AMLs (Walker & Held-Warmkessel, 2010).
- *Acute lymphocytic leukemia (ALL)* makes up about 10% of adult-onset leukemias and is most common in children. In adults with ALL, the Philadelphia chromosome, usually the hallmark of chronic myelogenous leukemia, may be present.
- *Chronic myelogenous leukemia (CML)* makes up about 20% of adult-onset leukemias, occurring more often in people older than 50 years. A major feature of CML is the presence of the Philadelphia chromosome abnormality in the leukemic cells. CML has three phases:
 - The *chronic phase* is often a slowly progressing (indolent) course during which the patient may have mild symptoms and respond to standard treatments. The bone marrow has less than 10% blast cells at this time.
 - The *accelerated phase* features spleen enlargement and progressive manifestation, such as intermittent fevers, night sweats, and unexplained weight loss. The patient usually does not respond to standard treatment and the bone marrow may contain 10% to 30% blast cells and promyelocytes. This phase typically lasts 6 to 12 months.
 - The *blast phase* indicates transformation to a very aggressive acute leukemia. The bone marrow contains more than 30% blast cells. The promyelocytes and blast cells spread to other tissues and organs.
- *Chronic lymphocytic leukemia (CLL)* is the most common type of chronic leukemia and occurs most often in people older than 50 years (Elphee, 2008). Average survival time ranges from less than 19 months for patients diagnosed with advanced disease to more than 10 years for patients diagnosed with early-stage disease.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A client newly diagnosed with acute leukemia asks why he is at such extreme risk for infection when his white blood cell count is so high. What is the nurse's best response?

- "Even though you have many white blood cells, they are too immature to fight infection."
- "For now, your risk is low; however, when the chemotherapy begins, your risk for infection will be high."
- "These white blood cells are cancerous and live longer than normal white blood cells, so they are too old to fight infection."
- "It is not the white blood cells that provide protection; it is the red blood cells, which are very low in your blood right now."

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask the patient about exposure to risk factors and related genetic factors. Age is important because the risk for adult-onset leukemia increases with age. Occupation and hobbies may reveal exposure to agents that increase the risk for leukemia. Previous illnesses and the medical history may reveal exposure to ionizing radiation or drugs that increase risk.

Changes in immune function increase the risk for infection in the patient with leukemia. Even when his or her blood may show a normal level of WBCs or even a high level, these cells are immature and cannot protect the patient from infection. Ask about the frequency and severity of infections, such as colds, influenza, pneumonia, bronchitis, or unexplained fevers, during the past 6 months.

Platelet function is reduced with leukemia. Ask about any excessive bleeding episodes, such as:

- A tendency to bruise easily
- Nosebleeds
- Increased menstrual flow
- Bleeding from the gums
- Rectal bleeding
- Hematuria (blood in the urine)
- Prolonged bleeding after minor abrasions or cuts

If the patient has experienced such an episode, ask whether this type and extent of bleeding is his or her usual response to injury or represents a change.

The patient with leukemia often has weakness and fatigue from anemia and from the increased metabolism of the leukemic cells. Ask whether any of these have occurred:

- Headaches
- Behavior changes
- Increased somnolence
- Decreased alertness
- Decreased attention span
- Lethargy, muscle weakness
- Loss of appetite
- Weight loss
- Increased fatigue

Listing activities in the previous 24 hours may reveal information about activity intolerance, changes in behavior, and

CHART 42-6 KEY FEATURES

Acute Leukemia**Integumentary Manifestations**

- Ecchymoses
- Petechiae
- Open infected lesions
- Pallor of the conjunctivae, nail beds, palmar creases, and around the mouth

Gastrointestinal Manifestations

- Bleeding gums
- Anorexia
- Weight loss
- Enlarged liver and spleen

Renal Manifestations

- Hematuria

Cardiovascular Manifestations

- Tachycardia at basal activity levels
- Orthostatic hypotension
- Palpitations

Respiratory Manifestations

- Dyspnea on exertion

Neurologic Manifestations

- Fatigue
- Headache
- Fever

Musculoskeletal Manifestations

- Bone pain
- Joint swelling and pain

unexplained fatigue. Determine how long the patient has had any of these debilitating symptoms.

Physical Assessment/Clinical Manifestations

Leukemia affects all blood cells and the health and function of all organs and systems. Thus many body areas and systems may be affected (Chart 42-6). The following manifestations occur with acute leukemia. Some may occur in the patient with chronic leukemia in the blast phase.

Cardiovascular changes are related to the adjustments the heart needs to make when oxygenation is reduced because of anemia. The heart rate is increased, and blood pressure is decreased. **Murmurs** (abnormal blood flow sounds through the heart) and **bruits** (abnormal blood flow sounds heard over arteries) may be heard. Capillary refill is slow. When the blood is highly viscous from a greatly elevated WBC count, blood pressure is elevated and the pulse is bounding.

Respiratory changes are related to reduced tissue oxygenation from anemia and to infection. Respiratory rate increases as anemia becomes more severe. If respiratory infections are present, the patient may have coughing and shortness of breath. Abnormal breath sounds are heard on auscultation.

Skin changes include pallor and coolness to the touch as a result of *reduced tissue perfusion* related to anemia. Pallor is most evident on the face, around the mouth, and in the nail beds. The conjunctiva of the eye also is pale, as are the creases on the palm of the hand (most evident when the skin over the palm of the hand is stretched). **Petechiae** (raised red spots) may be present on any area of skin surface, especially the legs and feet. The petechiae may be unrelated to any obvious trauma. Inspect for skin infections or injured areas that have failed to heal. Inspect the mouth for gum bleeding and any sore or lesion that may indicate infection.

Intestinal changes may be related to an increased bleeding tendency and to fatigue. Weight loss, nausea, and anorexia are common. Examine the rectal area for fissures, and test stool for occult blood. Many patients with leukemia have reduced

bowel sounds and are constipated because reduced blood flow to intestinal tissue leads to decreased peristalsis. Enlargement of the liver and spleen and abdominal tenderness also may be present from leukemic cells trapped in these organs.

Central nervous system (CNS) changes include cranial nerve problems, headache, and papilledema from leukemic invasion of the CNS. Seizures and coma also may occur.

Miscellaneous changes can include bone and joint tenderness as the marrow is damaged and the bone reabsorbs. Leukemic cells invade lymph nodes, causing enlargement.

Psychosocial Assessment

The patient with newly diagnosed leukemia is very anxious and fearful of the disease outcome. Current therapies have greatly improved the prognoses of leukemia. Spend time with the patient and family to assess what the diagnosis means to them and what they expect in the future. Without knowing the patient's expectations and feelings, you cannot teach him or her and provide individualized support.

A diagnosis of leukemia has serious consequences for a person's lifestyle. Hospitalization for initial treatment often lasts many weeks and may result in boredom, loneliness, isolation, and financial stress. Assess coping patterns, including activities that the patient finds enjoyable and methods that help the patient relax. After initial therapy, he or she may be able to resume work, depending on the occupation. Often the patient must make adjustments for changes in functional status. He or she is hospitalized repeatedly for complications.

Laboratory Assessment

The patient with acute leukemia usually has decreased hemoglobin and hematocrit levels, a low platelet count, and an abnormal white blood cell (WBC) count. The WBC count may be low, normal, or elevated. The patient with a high WBC count consisting mostly of blast cells at diagnosis has a poorer prognosis.

The definitive test for leukemia is an examination of cells obtained from bone marrow aspiration and biopsy

(Fig. 42-4). The bone marrow is full of leukemic **blast phase cells** (immature cells that are dividing). The proteins (**antigens**) on the surfaces of the leukemic cells help diagnose the type of leukemia. These proteins are “markers” that identify certain types of leukemia or may indicate prognosis. Such markers include the T11 protein, terminal deoxynucleotidyl transferase (TDT), the common acute lymphoblastic leukemia antigen (CALLA), and the CD33 antigen.

Blood clotting times and factors are usually abnormal with acute leukemia. Reduced levels of fibrinogen and other clotting factors are common. Clotting time is prolonged, as is the activated partial thromboplastin time (aPTT).

Chromosome analysis (cytogenetic studies) of the leukemic cells may identify marker chromosomes to help diagnose the type of leukemia, predict the prognosis, and determine therapy effectiveness. An example is the *Philadelphia chromosome*, which is important in the diagnosis and treatment of chronic myelogenous leukemia (CML).

Imaging Assessment

Specific manifestations determine the need for specific tests. For example, in a patient with dyspnea, a chest x-ray is needed to determine whether leukemic infiltrates are present in the lung. Skeletal x-rays may help determine whether bone **resorption** (loss of bone minerals and density) is present.

ANALYSIS

The priority problems for patients with acute myelogenous leukemia (AML), the most common type of adult leukemia, are:

1. Potential for infection related to decreased immune response and chemotherapy
2. Potential for injury related to thrombocytopenia and chemotherapy
3. Fatigue related to decreased tissue oxygenation and increased energy demands

PLANNING AND IMPLEMENTATION

Preventing Infection

Planning: Expected Outcomes. The patient with leukemia is expected to remain free from infection. Indicators include the following:

- Absence of fever and foul-smelling or purulent drainage
- Absence of cough, chest pain, and dyspnea
- Absence of urinary frequency, urgency, or pain and burning
- Intact skin and mucous membranes

Interventions. Infection is a major cause of death in the patient with leukemia because the white blood cells are immature and cannot function or the cells are depleted from chemotherapy, and sepsis is a common complication. Infection occurs through both **autocontamination** (normal flora overgrows and penetrates the internal environment) and **cross-contamination** (organisms from another person or the environment are transmitted to the patient). The three most common sources of infection are the skin, respiratory tract, and intestinal tract.

Gram-negative bacteria are the most common cause of infection, although other infections do occur. Interventions

CHART 42-7 FOCUSED ASSESSMENT

Patients at Risk for Infection

General Condition

- Age
- History of allergies
- History of chemotherapy, radiation therapy, or other immunosuppressive therapies, such as steroid use
- Chronic diseases
- History of febrile neutropenia and associated symptoms
- Nutritional status
- Functional status—problems with immobility
- Tobacco use—cigarettes, pipe, cigars, oral
- Recreational drug use
- Alcohol use
- Prescribed and over-the-counter drug use
- Baseline and ongoing vital signs—blood pressure, heart rate, respiratory rate, and temperature

Skin and Mucous Membranes

- Thorough inspection of all skin surfaces with attention to axilla, anorectal area, and under breasts; inspection of skin for color, vascularity, bleeding, lesions, edema, moist areas, excoriation, irritation, erythema; general condition of hair and nails, pressure areas, swelling, pain, tenderness, biopsy or surgical sites, wounds, enlarged lymph nodes, catheters, or other devices
- Inspection of oral cavity, including lips, tongue, mucous membranes, gingiva, teeth, and throat—color, moisture, bleeding, ulcerations, lesions, exudate, mucositis, stomatitis, plaque, swelling, pain, tenderness, taste changes, amount and character of saliva, ability to swallow, changes in voice, dental caries, patient's oral hygiene routine
- History of current skin or mucous membrane problems

Head, Eyes, Ears, Nose

- Pain, tenderness, exudate, crusting, enlarged lymph nodes

Cardiopulmonary

- Respiratory rate and pattern, breath sounds (presence/absence, adventitious sounds), quantity and characteristics of sputum, shortness of breath, use of accessory muscles, dysphagia, diminished gag reflex, tachycardia, blood pressure

Gastrointestinal

- Pain, diarrhea, bowel sounds, character and frequency of bowel movements, constipation, rectal bleeding, hemorrhoids, change in bowel habits, sexual practices, erythema, ulceration

Genitourinary

- Dysuria, frequency, urgency, hematuria, pruritus, pain, vaginal or penile discharge, vaginal bleeding, burning, lesions, ulcerations, characteristics of urine

Central Nervous System

- Cognition, level of consciousness, personality, behavior

Musculoskeletal

- Tenderness, pain, loss of function

Modified from Dean, G.E., Haeuber, D., & Rivera, L.M. (1996). Infection. In Grant, M., Frank-Stromborg, S.B., Baird, R., McCorkle, et al. (Eds.), *Cancer nursing: A comprehensive textbook* (2nd ed., p. 975). Philadelphia: Saunders.

aim to halt infection and control infections early. **Chart 42-7** lists areas to assess for the patient at risk for infection.

Drug Therapy for Acute Leukemia. Drug therapy for patients with AML is divided into three distinctive phases: induction, consolidation, and maintenance.

Induction therapy is intense and consists of combination chemotherapy started at the time of diagnosis. The purpose of this therapy is to achieve a rapid, complete remission of all manifestations of disease. Combination of chemotherapeutic agents such as an anthracycline (idarubicin or daunorubicin) or anthracenedione (mitoxantrone) and cytosine arabinoside (cytarabine) are usually prescribed although agencies and physicians differ in drugs used and the treatment schedule. One example prescribed course of aggressive chemotherapy is continuous IV cytosine arabinoside for 7 days together with a brief infusion of daunorubicin for the first 3 days, sometimes referred to as a “7 plus 3” regimen. A side effect of this therapy is severe bone marrow suppression with neutropenia, making the patient even more at risk for infection.

Prolonged hospitalizations are common while the patient is neutropenic. Recovery of bone marrow function requires at least 2 to 3 weeks, during which time the patient must be protected from life-threatening infections. Other side effects of drugs used for induction therapy include nausea, vomiting, diarrhea, alopecia (hair loss), stomatitis (mouth sores), kidney toxicity, liver toxicity, and cardiac toxicity. (See Chapter 24 for information on effects of anticancer agents.) Older patients have a greater infection-related death rate during this phase than do younger patients.

Consolidation therapy often consists of another course of either the same drugs used for induction at a different dosage or a different combination of chemotherapy drugs. This treatment occurs early in remission, and its intent is to cure. Consolidation therapy may be either a single course of chemotherapy or repeated courses. Hematopoietic stem cell transplantation also may be considered, depending on the disease subtype and the patient's response to induction therapy.

Maintenance therapy may be prescribed for months to years after successful induction and consolidation therapies. It is used for patients with acute lymphocytic leukemia (ALL) and acute promyelocytic leukemia (APL). The purpose is to maintain the remission achieved through induction and consolidation. Maintenance drugs for ALL are milder and are often given orally for 2 to 5 years. Not all types of leukemia respond to maintenance therapy.

Drug Therapy for Chronic Leukemia. Imatinib mesylate (Gleevec) is a common first-line drug therapy for CML that is Philadelphia chromosome positive. It is targeted therapy that prevents the activation of an enzyme (tyrosine kinase) needed for growth of CML cells. This oral drug is well tolerated and has been effective at inducing remission for early stages of CML. Other drugs used to treat CML include interferon alpha, which reduces the growth of leukemic cells, but its use is limited because of side effects, such as flu-like symptoms and fevers. For patients whose leukemia is resistant to imatinib, second-line therapy with dasatinib (Sprycel) or nilotinib (Tasigna) may be prescribed (Bauer & Romvari, 2009; Byar & Workman, 2012).

Treatment of chronic lymphocytic leukemia (CLL) with standard chemotherapy can cause remissions but does not cure the disease. The decision to initiate therapy is based on disease stage, symptoms, and disease activity. Available options include treatment with an alkylating agent such as chlorambucil with or without prednisone; fludarabine; and

combined chemotherapy such as CVP (cyclophosphamide, vincristine, prednisone). Rituximab (Rituxan) is often combined with these treatments or used as a single agent. A new targeted agent, ofatumumab (Arzerra), has recently been approved for use in CLL that does not respond to fludarabine and alemtuzumab (Smart, 2010). Another drug under investigation for management of CLL that has relapsed or does not respond to other treatment is lenalidomide (Revlimid) (Miller et al., 2010).

Hematopoietic stem cell transplantation in patients with CLL is an option that offers curative potential or prolonged disease-free survival. However, it comes with considerable risk for mortality and is not an appropriate alternative for all patients.

New drugs, such as bendamustine (Treanda), an alkylating agent with antimetabolite properties, may be used alone or along with rituximab (Rituxan) for CLL. In addition to rituximab, other monoclonal antibodies are approved for CLL, such as ofatumumab (Arzerra) and alemtuzumab (Campath). In addition, a number of emerging therapies are under investigation for the treatment of CLL, such as oblimersen (Genasense) and flavopiridol.

Drug Therapy for Infection. Drug therapy is the main defense against infections that develop in patients undergoing therapy for AML. Drugs used depend on the sensitivity of the organism causing the infection, as well as infection severity. Drugs for infection are classified as antibacterial, antiviral, or antifungal.

Antibiotic and antibacterial drugs used for prevention or treatment of infection in patients with AML usually include an aminoglycoside antibiotic (amikacin, gentamicin, and tobramycin) and a penicillin, or a third-generation cephalosporin (ceftazidime). Additional powerful antibiotics used may include vancomycin in cases of methicillin-resistant *Staphylococcus aureus* (MRSA) or if indwelling venous catheter infection is suspected.

Systemic antifungal drugs are used when a fungal infection has been diagnosed or is strongly suggested or when a neutropenic patient remains febrile 4 to 7 days after starting antibiotic therapy. Common antifungal drugs include amphotericin B, ketoconazole (Nizoral), voriconazole (Vfend), fluconazole (Diflucan), and nystatin (Mycostatin, Nadostine ♣, Nilstat).

Antiviral drugs are used in patients with leukemia to prevent and treat viral infections. Acyclovir is given at the start of chemotherapy, especially for patients who are cytomegalovirus (CMV) positive. If a viral infection is suspected or diagnosed, drug therapy may include ganciclovir, foscarnet, or steroids. The antivirals, although helpful in combating severe infections, have serious adverse effects, especially **ototoxicity** (impaired hearing and/or balance) and **nephrotoxicity** (impaired kidney function). Carefully monitor the patient treated with such drugs for signs of hearing impairment and kidney problems.

Infection Protection. A major focus in caring for the patient with leukemia is protection from infection. All personnel must use extreme care during all nursing procedures. Frequent, thorough handwashing is of the utmost importance. Anyone with an upper respiratory tract infection who must enter the patient's room must wear a mask. Observe strict asepsis when changing dressings or accessing a central

venous catheter. Maintain strict aseptic technique in the care of these catheters at all times.

If possible, ensure that the patient is in a private room to reduce cross-contamination. Other precautions are used, such as not allowing standing water in vases, denture cups, or humidifiers in the patient's room, because they are breeding grounds for organisms.

Some facilities prescribe a "minimal bacteria diet" during the neutropenic period. Any uncooked foods, such as raw fruits and vegetables, are removed from the diet because they contain large numbers of organisms. There is no clear benefit to patients with this diet.

Some facilities place the immunosuppressed patient in a room with a high-efficiency particulate air (HEPA) filtration or laminar airflow system. These systems decrease the number of airborne pathogens. It is not known whether these systems benefit patients.

Continually assess the patient for infection. This task is difficult because manifestations may not be obvious in the patient with leukopenia. The development of fever and the formation of pus (both indicators of infection) depend on the presence of WBCs. The patient with leukopenia may have a severe infection without pus and with only a low-grade fever.

Monitor the patient's daily CBC with differential WBC count and absolute neutrophil count (ANC). Inspect the mouth during every shift for lesions and mucosa breakdown. Assess the lungs every 8 hours for crackles, wheezes, and reduced breath sounds. Assess urine for odor and cloudiness. Ask about any urgency, burning, or pain on urination. Take vital signs at least every 4 hours to assess for fever.

! NURSING SAFETY PRIORITY

Critical Rescue

A temperature elevation of even 1° F (or 0.5° C) above baseline is significant for a patient with leukopenia and indicates infection until it has been proven otherwise. Report this finding to the health care provider at once.

Many hospital units that specialize in the care of patients with neutropenia have specific protocols for antibiotic therapy if infection is suspected. Usually, the health care provider is notified immediately and specific specimens are obtained for culture. Obtain blood for bacterial and fungal cultures from peripheral sites and from the central venous catheter (Myers & Reyes, 2011). Obtain urine specimens, sputum specimens, and specimens from open lesions for culture. Chest x-rays are taken. After the specimens are obtained, the patient begins IV antibiotics.

Skin care is important for preventing infection in the patient with leukemia because the skin may be the only intact defense. Teach him or her about hygiene, and urge daily bathing. If the patient is immobile, turn him or her every hour and apply skin lubricants.

Perform pulmonary hygiene every 2 to 4 hours. Listen to the lungs for crackles, wheezes, and reduced breath sounds. Urge the patient to cough and deep breathe or to perform sustained maximal inhalations every hour while awake.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client with leukemia to prevent an infection by autocontamination?

- A. Take antibiotics exactly as prescribed.
- B. Perform mouth care three times daily.
- C. Avoid the use of pepper and raw foods.
- D. Report any burning on urination immediately.

Hematopoietic Stem Cell Transplantation. Hematopoietic stem cell transplantation (HSCT), sometimes called *bone marrow transplantation (BMT)*, is standard treatment for the patient with leukemia who has a closely matched donor and who is in temporary remission after induction therapy. HSCT is used also for lymphoma, multiple myeloma, aplastic anemia, sickle cell disease, and many solid tumors.

The bone marrow is the site of production of leukemic cells. It can be difficult to ensure that all leukemic cells have been eradicated during induction therapy. Therefore before an HSCT, additional chemotherapy with or without total body irradiation is given to purge (condition or clean) the marrow of leukemic cells. *These treatments are lethal to the bone marrow, and without replacement of stem cells by transplantation, the patient would die of infection or hemorrhage.*

After conditioning, new healthy stem cells are given to the patient. The new cells go to the marrow and then begin the process of hematopoiesis, which results in normal, properly functioning cells and, ideally, a permanent cure.

Transplant units are present in many hospitals. With long-term survival increasing after transplantation, nurses can expect to be caring for these people—if not during the actual transplantation or recovery period, then after the recovery period—in a variety of health care settings.

HSCT started with the use of **allogeneic bone marrow transplantation** (transplantation of bone marrow from a sibling or matched unrelated donor) and has advanced to the use of human leukocyte antigen (HLA)-matched stem cells from the umbilical cords of unrelated donors. Transplants are classified by the source of stem cells. In **autologous transplants**, patients receive their own stem cells (which were collected before high-dose therapy). **Syngeneic transplants** are those with the stem cells taken from the patient's identical sibling. In **allogeneic transplants**, a closely HLA-matched sibling or an unrelated but matched donor provides the stem cells. Stem cells for transplantation may be obtained by bone marrow harvest, peripheral stem cell pheresis, or umbilical cord blood stem cell banking. Table 42-2 lists the types of transplants.

Transplantation has five phases: stem cell obtainment, conditioning regimen, transplantation, engraftment, and post-transplantation recovery.

Obtaining the Stem Cells. Stem cells are taken either from the patient directly (autologous stem cells) or from an HLA-matched person (allogeneic stem cells). For allogeneic transplant, a donor is selected from family members tested for HLA type. The best results occur when the donor is an HLA-identical sibling; however, transplant also can be successful between those with closely matched HLA types. The chance of matching with any given sibling is 25%.

TABLE 42-2 CLASSIFICATION OF TRANSPLANTS

TYPE OF TRANSPLANT	SOURCES OF STEM CELLS
Autologous	
Self-donation	Bone marrow harvest Peripheral stem cell pheresis Umbilical cord blood
Syngeneic	
Patient's HLA identical twin	Bone marrow harvest Peripheral stem cell pheresis
Allogeneic	
HLA-matched relative	Bone marrow harvest
Unrelated HLA-matched donor	Peripheral stem cell pheresis
Mismatched or partially HLA-matched family member or unrelated donor (donor registries)	Umbilical cord blood

HLA, Human leukocyte antigen.

CULTURAL AWARENESS

About 70% of people on the bone marrow donor lists are white. The chance of finding an HLA-matched unrelated donor is estimated at 30% to 40% for white people, but for African Americans the chance is less than 20% because there are fewer African Americans among registered donors. Although blood types are common in all racial groups, tissue types can be very different among racial and ethnic groups. Nationally, efforts are made to publicize the need for donors from all cultural backgrounds. Research in this area has identified several potential barriers to stem cell donation among African Americans. These include fear or not trusting the system, concern about costs to the donor, and concern that the recipient may be a drug abuser or person who would not appreciate the sacrifice of a donation. Targeted education efforts may reduce these barriers.

Donor registries keep records of potential donors who can provide stem cells for patients who do not have a family member HLA match. The chance of matching with an unrelated donor is 1 in 5000.

Bone marrow harvesting occurs after a suitable donor is identified by tissue typing. The procedure occurs in the operating room, where marrow is removed through multiple aspirations from the iliac crests, although this technique is used less often today. About 500 to 1000 mL of marrow is aspirated. This amount is about 5% to 10% of the donor's marrow supply and regrows within a few weeks. The marrow is then filtered and, if autologous, is treated to rid the marrow of any remaining cancer cells. Allogeneic marrow is transfused into the recipient immediately. Autologous marrow is frozen for later use.

Monitor the donor for manifestations of fluid loss, assess for complications of anesthesia, and manage pain. During surgery, donors may lose a large amount of fluid in addition to the volume of marrow taken. Donors are hydrated with saline infusions before and after surgery. Occasionally the donor may need an RBC transfusion. Assess the harvest sites to ensure that the donor is not bleeding excessively.

Marrow donation is usually a same-day surgical procedure. Teach the donor to inspect the harvest sites for bleeding

and to take analgesics for pain. Pain at the harvest sites (hips) is common and is managed with oral non-aspirin-containing analgesics. Some donors may require opioid analgesics for pain control.

Peripheral blood stem cell (PBSC) harvesting requires three phases: mobilization, collection by pheresis, and reinfusion. **PBSCs** are stem cells that have been released from the bone marrow and circulate within the blood. Although there are fewer stem cells in peripheral blood than in bone marrow, their numbers can be artificially increased. During the mobilization phase, chemotherapy or hematopoietic growth factors are given to the patient for an autologous collection, depending on the cancer type, and hematopoietic growth factors alone are given to the donor for an allogeneic collection (Devine et al., 2010). These agents increase the numbers of stem cells and WBCs in the peripheral blood. A new agent approved to mobilize stem cells before harvesting is plerixafor (Mozobil). After mobilization, the stem cells are then collected by **pheresis** (withdrawing whole blood, filtering out the cells, and returning the plasma to the patient). One to five pheresis procedures, each lasting 2 to 4 hours, are needed to obtain enough stem cells for transplantation. The cells are frozen and stored for reinfusion after the patient's conditioning regimen is completed.

Monitor the patient or donor closely during pheresis. Complications include catheter clotting and hypocalcemia (caused by anticoagulants). Low calcium levels may cause numbness or tingling in the fingers and toes, abdominal or muscle cramping, or chest pain. Oral calcium supplements may be used to manage these symptoms. Monitor vital signs at least every hour during pheresis. The patient may become hypotensive from fluid loss during the procedure.

Cord blood harvesting involves obtaining stem cells from umbilical cord blood of newborns. This blood has a high concentration of stem cells. Umbilical stem cells are obtained through a simple blood draw from the placenta. After birth, before the placenta detaches, a syringe is used to withdraw 40 to 150 mL of blood from the umbilical vein of the placenta. The syringes are placed in a kit and returned to the Cord Blood Registry for processing and storage. The stem cells may be used later for an unrelated recipient or stored in case the infant develops a serious illness later in life and needs them. The cost of banking and processing umbilical cord stem cells is about \$1500, with an additional charge of \$200 per year for storage. Umbilical stem cells can last for years when stored properly in liquid nitrogen.

Conditioning Regimen. Fig. 42-5 outlines the timing and steps involved in transplantation. The day the patient receives the stem cells is day T=0. Before transplantation, the conditioning days are counted in reverse order from T=0, just like a rocket countdown. After transplantation, days are counted in order from the day of transplantation.

The patient first undergoes a conditioning regimen, which varies with the diagnosis and type of transplant to be received. The conditioning regimen serves two purposes: (1) to "wipe out" the patient's own bone marrow (**myeloablation**), thus preparing him or her for optimal graft take; and (2) to give higher-than-normal doses of chemotherapy and/or radiotherapy to rid the person of cancer cells. Usually a period of 5 to 10 days is required. The regimen usually includes high-dose chemotherapy and sometimes includes total-body irradiation (TBI). Each conditioning regimen is individually

FIG. 42-5 Timing and steps of allogeneic bone marrow transplantation.

tailored, with the patient's specific disease, overall health, and previous treatment considered. A typical conditioning regimen for an adult with acute myelogenous leukemia (AML) receiving an allogeneic HSCT for treatment is:

- *Days T-5 through T-4:* High-dose chemotherapy to obliterate the patient's own bone marrow cells and to kill off any remaining leukemic cells. Specific agents include thiotepe, busulfan, carmustine, cyclophosphamide, cytosine arabinoside, etoposide, and melphalan. The dosages are much higher than those used for normal chemotherapy.
- *Days T-3 through T-1:* Delivery of TBI. The total radiation dose for TBI is 1200 rads given as 200 rads twice daily over 3 days. (TBI is not used in all facilities for all patients.)

Because of the problems and risk for death associated with this conditioning regimen, a non-myeloablative approach may be used instead. Non-myeloablative regimens use lower doses of chemotherapy and/or lower dose of TBI that allow for recovery of a recipient's own immune system. The use of non-myeloablative conditioning regimens decreases the chemotherapy side effects but relies on the development of graft-versus-host disease (GVHD) for the control of the cancer. In contrast, myeloablative conditioning regimens use high doses of chemotherapy with or without radiation therapy to completely destroy a recipient's bone marrow, allowing for replacement by a new immune system. There are many variations in non-myeloablative conditioning regimens.

During conditioning, bone marrow and normal tissues respond immediately to the chemotherapy and radiation. The patient has all of the expected side effects associated with both therapies. When chemotherapy is given in high doses, these side effects are more intense than those seen with standard doses. Side effects include nausea and vomiting, mucositis, capillary leak syndrome, diarrhea, and bone marrow suppression.

Late effects from the conditioning regimen are also common, occurring as late as 3 to 10 years after transplantation. These problems include veno-occlusive disease (VOD), skin toxicities, cataracts, lung fibrosis, second cancers, cardiomyopathy, endocrine complications, and neurologic complications.

Transplantation. Day T-0 is the day of transplantation. The transplantation itself is very simple. Frozen marrow, PBSCs, or umbilical cord blood cells are thawed and then infused through the patient's central catheter like an ordinary blood transfusion.

! NURSING SAFETY PRIORITY

Action Alert

Do not use blood administration tubing to infuse stem cells because the cells could get caught in the filter, resulting in the patient receiving fewer stem cells.

Side effects of all types of stem cell transfusions are similar. The patient may have fever and hypertension as a reaction to the preservative used in stem cell storage. To prevent these reactions, acetaminophen (Tylenol), hydrocortisone, and diphenhydramine (Benadryl) are given before the infusion. Antihypertensives or diuretics may be needed to treat fluid volume changes. The patient may have red urine for a short time as a result of red blood cell breakage in the infused stem cells.

Engraftment. The transfused PBSCs and marrow cells circulate briefly in the peripheral blood. The stem cells find their way to the marrow-forming sites of the patient's bones and establish residency there. How the donated stem cells "home in" on the bone marrow sites is not yet understood.

Engraftment, the successful "take" of the transplanted cells in the patient's bone marrow, is key to the whole transplantation process. For the donated marrow or stem cells to "rescue" the patient after large doses of chemotherapy or radiotherapy have wiped out his or her own bone marrow, the transfused stem cells must survive and grow in the patient's bone marrow sites. Engraftment takes 8 to 12 days for peripheral blood stem cell transplantation and 12 to 28 days for bone marrow stem cell transplantation. To aid engraftment, growth factors, such as granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor, may be given. When engraftment occurs, the patient's WBC, RBC, and platelet counts begin to rise.

Monitoring of engraftment involves checking the patient's blood for "chimerism," which is the presence of blood cells that show a genetic profile or other marker that is different from those of the patient. Early mixed chimerism is the presence of both the patient's cells and those of the donor. Progressive chimerism with increasing percentages of donor cells indicates engraftment. Regressive chimerism with increasing percentages of the patient's cells indicates graft failure. When engraftment is completely successful, only the donor's cells are present.

Prevention of Complications. The period after transplantation is difficult. Infection and bleeding are severe problems because the patient remains without any natural immunity

EVIDENCE-BASED PRACTICE

Why Don't They Use the Evidence?

Bevans, M., Tierney, D.K., Bruch, C., Burgunder, M., Castro, K., Ford, R., et al. (2009). Hematopoietic stem cell transplantation nursing: A practice variation study. *Oncology Nursing Forum*, 36(6), E317-E325.

Hematopoietic stem cell transplantation (HSCT) is a life-saving procedure for some malignancies that has been performed successfully for four decades. The procedure itself is dangerous, and many patients die either during the transplant period or within the first few months after the procedure. The most common cause of HSCT death is infection. Thus prevention of infection in this population is a critical practice focus for all members of the health care team. Guidelines for effective infection control measures for this population were developed based on evidence, published in 2000, and set as a standard for practice among HSCT centers in the United States. The purpose of the current study was to identify what variations from the standard of practice for infection control in the HSCT population exist.

Using a convenience sample, the study surveyed 205 HSCT nurses who were members of the Bone and Marrow Stem Cell Transplant Special Interest Group of the Oncology Nursing Society for compliance with the recommended infection control guidelines. Survey results indicated that during the hospitalization period, minimal variation in actual practice from the recommendations occurred. The areas of practice in which there was identified variation were those related to dietary restrictions, personal hygiene (patients), and social interaction. In the posthospitalization phase, greater variation from practice standards were reported, although the areas of specific practice variation remained the same as in the hospitalization phase. The researchers postulated that a possible contributor to practice variation in the posthospitalization phase was the lack of detail in the recommended practices with regard to the length of time the practices should remain in effect.

Level of Evidence: 4

The study method was descriptive, using a researcher-developed questionnaire. The number of subjects was large and representative of nurses specializing in care of patients undergoing HSCT.

Commentary: Implications for Practice and Research

Although this study was not experimental in design, its importance to evidence-based practice in nursing should not be underestimated. The specialty of HSCT nursing is relatively new, and the patients are at high risk for life-threatening infection for weeks to months. Evidence-based practice standards have been established but are not consistently followed, particularly in the home environment. Part of the identified gap in practice was related to the length of time post-hospitalization that the recommended practices should be used. This time is beyond the acute neutropenic period, but patients are still at risk for infection because full recovery of immune function takes many months. Although HSCT nurses were aware of the recommendations and indicated consistent belief in the need for continuing implementation, the importance of the practices appears to be not sufficiently communicated to patients and families.

until the transfused stem cells grow and engraft. The nursing care for this patient is the same as for the patient during induction therapy for AML. Helping the patient maintain hope through this long recovery period is difficult. Complications are often severe and life threatening. Standards of practice for prevention of infection after HSCT have been established based on evidence. However, there is considerable variation in implementation of these recommendations (Bevans et al., 2009). Inconsistencies in practices may interfere with positive patient outcomes of HSCT (see the Evidence-Based Practice box above). Help the patient have a positive attitude and be involved in his or her own recovery.

In addition to the problems related to the period of **pancytopenia** (too few circulating blood cells), other complications of HSCT include failure to engraft, development of graft-versus-host disease (GVHD), and veno-occlusive disease (VOD).

Failure to engraft occurs when the donated stem cells fail to grow in the bone marrow and function properly. This issue is discussed in advance with the patient and the donor. Failure to engraft occurs more often with transplants using allogeneic stem cells than with those using autologous stem cells. The causes include too few living cells transplanted, attack or rejection of donor cells by the remaining immune system cells of the recipient, infection of transplanted cells, and unknown biologic factors. *If the transplanted cells fail to engraft, the patient will die unless another transplant with stem cells is successful.*

**DECISION-MAKING CHALLENGE****Patient-Centered Care; Teamwork and Collaboration**

The patient is a 32-year-old woman with acute lymphocytic leukemia. After successful induction therapy, she received a bone marrow transplant with cells donated by her only sibling, a 27-year-old sister. The first transplant failed to engraft. The patient was transplanted a second time with cells donated by the same sister. It is now 5 weeks after the second transplant and there are no indications of engraftment. A third transplant is planned but the sister is reluctant to donate again because she is worried that bone marrow donation may decrease her chances of ever becoming pregnant. The parents of the two sisters are astounded that the younger daughter appears willing to let her sister die rather than go through another bone marrow harvesting procedure.

1. How should the patient, parents, and donating sister be approached and by whom?
2. Legally, should this sister be asked to donate again?
3. In what way does bone marrow harvesting affect fertility?

Graft-versus-host disease (GVHD) occurs mostly in allogeneic transplants but also can occur in autologous transplants (Baker, 2010). The immunocompetent cells of the donated marrow recognize the patient's cells, tissues, and organs as foreign and start an immunologic attack against them. The graft is actually attacking the host tissues and cells.

Although all host tissues can be attacked and harmed, the tissues usually damaged are the skin, intestinal tract, and liver. Fig. 42-6 shows the typical skin appearance of GVHD. About 25% to 50% of all allogeneic HSCT recipients have some degree of GVHD, and more than 15% of the patients who develop GVHD die of its complications. The presence of some GVHD indicates successful engraftment.

Management of GVHD involves limiting the activity of donor T-cells by using drugs to suppress immune function such as cyclosporine, tacrolimus, methotrexate, corticosteroids, mycophenolate mofetil (Cellcept, MMF), and antithymocyte globulin (ATG). Care is taken to avoid suppressing the new immune system to the extent that either infection risk increases or the new cells stop engrafting.

Veno-occlusive disease (VOD) is the blockage of liver blood vessels by clotting and inflammation (phlebitis). This problem occurs in up to 20% of patients who undergo HSCT and is the most serious. Problems usually begin within the first 30 days after transplantation. Patients who received high-dose

FIG. 42-6 Typical skin manifestations of graft-versus-host disease (GVHD).

chemotherapy, especially alkylating agents, are at risk for life-threatening liver complications. Manifestations include jaundice, pain in the right upper quadrant, ascites, weight gain, and liver enlargement.

Because there is no known way of opening the liver vessels, treatment is supportive. Early detection improves the chance for survival. Fluid management is also crucial. Assess the patient daily for weight gain, fluid retention, increases in abdominal girth, and hepatomegaly.

Minimizing Injury

Normal bone marrow production of platelets is severely limited with acute myelogenous leukemia (AML), leading to thrombocytopenia. The patient is at great risk for excessive bleeding in response to minimal trauma. Thrombocytopenia can also be caused by induction therapy for AML or high-dose chemotherapy for transplantation.

Planning: Expected Outcomes. The patient with leukemia is expected to remain free from bleeding. Indicators include:

- Maintenance of hematocrit and hemoglobin within normal ranges
- Absence of visible bleeding, petechiae, or ecchymosis
- Absence of evidence of occult bleeding (e.g., abdominal swelling, tarry stools)

Interventions. The patient's platelet count is decreased as a side effect of chemotherapy. During the period of greatest bone marrow suppression (the **nadir**), the platelet count may be very low (less than 10,000/mm³). He or she is at extreme risk for bleeding once the platelet count falls below 50,000/mm³, and spontaneous bleeding often occurs when the platelet count is lower than 20,000/mm³.

Bleeding Precautions are used to protect the patient at increased risk for injury from bleeding ([Chart 42-8](#)). Assess

CHART 42-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient with Thrombocytopenia

- Handle the patient gently.
- Use a lift sheet when moving and positioning in bed.
- Avoid IM injections and venipunctures.
- When injections or venipunctures are necessary, use the smallest-gauge needle for the task.
- Apply firm pressure to the needle stick site for 10 minutes or until the site no longer oozes blood.
- Apply ice to areas of trauma.
- Test all urine and stool for the presence of occult blood.
- Observe IV sites every 2 hours for bleeding.
- Avoid trauma to rectal tissues:
 - Do not give enemas.
 - Administer well-lubricated suppositories with caution.
 - Advise patient not to have anal intercourse.
- Measure abdominal girth daily.
- Advise the patient to use an electric shaver.
- Teach the patient to avoid mouth trauma:
 - Use soft-bristled toothbrush or tooth sponges.
 - Do not floss between teeth.
 - Avoid dental work, especially extractions.
 - Avoid hard foods.
 - Make sure that dentures fit and do not rub.
- Encourage the patient not to blow the nose or insert objects into the nose.
- Advise the patient to avoid contact sports.
- Teach the patient to wear shoes with firm soles when ambulating.

him or her at least every 4 hours for evidence of bleeding: oozing, enlarging bruises, petechiae, or purpura. Inspect all stools, urine, drainage, and vomit for blood, and test for occult blood. Measure any blood loss as accurately as possible, and measure the abdominal girth daily. Increases in abdominal girth can indicate internal hemorrhage. Institute the Bleeding Precautions listed in [Chart 42-8](#). Platelet levels return to normal more slowly than do either WBCs or RBCs, and the patient remains at risk for bleeding for weeks after discharge from the transplant unit.

Monitor laboratory values daily. Review CBC results daily to determine the risk for bleeding, as well as actual blood loss. The patient with a platelet count below 10,000/mm³ may need a platelet transfusion. For the patient with severe blood loss, packed RBCs may be prescribed (see discussion on pp. 899-900 in the [Red Blood Cell Transfusions](#) section).

Conserving Energy

Normal production of red blood cells is limited in leukemia, causing anemia, which results in fatigue. Also, leukemic cells have high rates of metabolism, increasing fatigue in the anemic patient with leukemia. Anemia may also occur as a side effect of chemotherapy.

Planning: Expected Outcomes. The patient with leukemia is expected to have no increase in fatigue. Indicators include that the patient consistently demonstrates these behaviors:

- Participates in self-care
- Recognizes symptoms of fatigue
- Changes activity level to match energy level

Interventions. Interventions to reduce fatigue include those that conserve energy and improve RBC counts.

Nutrition therapy is needed to assist the patient to eat enough calories to meet at least basal energy requirements. However, increasing food intake can be difficult when he or she is fatigued. Collaborate with a dietitian to provide small, frequent meals high in protein and carbohydrates. Food items that are liquid or semisolid require less effort to eat.

Blood transfusions are sometimes indicated for the patient with fatigue. Transfusions increase the blood's oxygen-carrying capacity and replace missing RBCs. For the patient with fatigue related to anemia, packed RBCs are the blood component choice. (See [Chart 42-13](#) on p. 898 for nursing care during transfusions.)

Drug therapy with colony-stimulating growth factors may be used to reduce the severity and duration of anemia and neutropenia after intensive chemotherapy for lymphoid malignancies. For anemia, erythropoiesis-stimulating agents (ESAs) that boost production of RBCs may be used. These agents now carry a warning that they may cause hypertension and increase the risk for myocardial infarction. ESAs must be given with care and should be avoided in patients with myeloid malignancies. They are not used unless the hemoglobin level is lower than 10 mg/dL. When indicated, subcutaneous injections of epoetin alfa (Epogen or Procrit) are given weekly or every 2 weeks or darbepoetin alfa (Aranesp) is given subcutaneously weekly to every 3 weeks until hemoglobin levels reach 10 mg/dL. The agents cause a stinging sensation when injected. Assess for side effects such as hypertension, headaches, fever, [myalgia](#) (muscle aches), and rashes. (See [Chapter 24](#) for information on hematopoietic growth factors.)

Activity management is needed to help conserve the patient's energy ([Chart 42-9](#)). Examine the patient's schedule of prescribed and routine activities. Assess those activities that do not have a direct positive effect on the patient's condition in terms of their usefulness. If the benefit of an activity is less than its worsening of fatigue, coordinate with other members of the health care team about eliminating or postponing it. Activities that may be postponed include physical therapy and invasive diagnostic tests not needed for assessment or treatment of current problems.

Community-Based Care

The patient with leukemia is discharged after induction chemotherapy and recovery of blood cell production. Follow-up care continues on an outpatient basis. Although many transplant centers discharge patients after engraftment, some centers give high-dose chemotherapy and stem cell infusion on an outpatient basis. This plan involves daily clinic visits and frequent follow-up by nurses in the home care setting.

Home Care Management

Planning for home care for the patient with leukemia begins as soon as remission is achieved. Assess the available support mechanisms. Many patients need a visiting nurse to assist with dressing changes for central venous catheters, nutritional infusions, and platelet infusions and to answer questions. Home transfusion therapy for blood components may be needed.

Coordination of the home care team is critical for the patient receiving stem cell transplantation in the home setting. Potential candidates are evaluated in advance. Criteria include a knowledgeable caregiver, a clean home

CHART 42-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Conserving Energy

- Reassure the patient that fatigue is temporary and energy levels will improve over a period of weeks to months. Stress that a return to previous energy levels may take as long as a year.
- Teach the patient that shortness of breath and palpitations are symptoms of over-activity.
- Instruct the patient to stop activity when shortness of breath or palpitations are present.
- Space care activities at least an hour apart, and avoid the time right before or right after meals.
- Schedule care activities at times when the patient has more energy (e.g., immediately after naps).
- Perform complete bed bath only every other day. In between complete baths, ensure cleansing of face, hands, axillae, and perineum.
- In collaboration with other members of the health care team, cancel or reschedule non-essential tests and activities.
- Provide four to six small, easy-to-eat meals instead of three larger ones.
- Urge the patient to drink small amounts of protein shakes or other nutritional supplements.
- During periods of extreme fatigue, encourage the patient to allow others to perform personal care.
- Help the patient identify one or two lead visitors (those designated as able to visit at any time and who do not disturb the patient).
- Selectively limit non-lead visitors when the patient is resting or sleeping.
- Remind families that, although independence is important, independence in ADLs during extreme fatigue can be detrimental to the patient's health.
- Monitor oxygen saturation and respiratory rate during any activity to determine patient responses and activity tolerance.

environment, location near the hospital, telephone access, and emotional stability of the patient and caregiver.

Home care nurses give chemotherapy and monitor the patient for complications. Nurses visit the patient once or twice per day and spend between 4 and 8 hours per day in the home. The patient receives the stem cell transplant infusion in the outpatient clinic. Nursing care is similar to that provided in the hospital. If complications such as sepsis or veno-occlusive disease (VOD) occur, the patient is admitted to the inpatient facility.

Teaching for Self-Management

Instruct the patient and family about the importance of continuing therapy and medical follow-up. Many patients go home with a central venous catheter in place and need instructions about its care. [Chart 42-10](#) lists guidelines for central venous catheter care at home. These guidelines may be altered depending on the home setting, assistance available, and agency policy.

Protecting the patient from infection at home is just as important as it was during hospitalization. (See [Chart 42-7](#) for focused assessment for the patient at risk for infection.) Urge the patient to use proper hygiene and to avoid crowds or others with infections. Neither the patient nor any household member should receive live virus immunization (poliomyelitis, measles, or rubella) for 2 years after transplantation or while taking immunosuppressive drugs. Instruct the patient to continue mouth care regimens at home. Stress to the

CHART 42-10 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Home Care of the Central Venous Catheter

- To maintain patency, flush the catheter briskly with saline once a day and after completing infusions.
- Change the Luer-Lok cap on each catheter lumen weekly.
- Change the dressing as often as prescribed:
 - Use clean technique with thorough handwashing.
 - Clean the exit site with alcohol and povidone-iodine (Betadine) or with chlorhexidine.
 - Apply antibacterial ointment to the site, if prescribed.
 - Cover the site with dry sterile gauze dressing, taped securely, or with transparent adherent dressing.
- To prevent tension, always tape the catheter to yourself.
- Look for and report any signs of infection (redness, swelling, or drainage at the exit site).
- In case of a break or puncture in the catheter lumen, immediately clamp the catheter between yourself and the opening. *Notify your physician immediately.*

patient that he or she should immediately notify the physician if a fever or any other sign of infection develops. [Chart 42-11](#) lists guidelines for patients for infection prevention.

Many patients return home still at risk for bleeding because platelet recovery is slower than recovery of white blood cells (WBCs). Reinforce safety and bleeding precautions, and emphasize that these precautions must be followed until the platelet count is above 50,000/mm³. Teach the patient and family to assess for petechiae, avoid trauma and sharp objects, apply pressure to wounds for 10 minutes, and report blood in the stool or urine or headache that does not respond to acetaminophen. [Chart 42-12](#) lists guidelines for patients at risk for bleeding.

Psychosocial Preparation

A diagnosis of leukemia threatens self-esteem and the family role. The patient faces the possibility of death, and treatment causes major changes in self-image. Changes occur in his or her body image, level of independence, and lifestyle. Some feel threatened by the environment, seeing everything as potentially infectious. Patients who are cared for in protective isolation may feel lonely and isolated. Help the patient and family define priorities, understand the illness and its treatment, and find hope. Make referrals to support groups sponsored by organizations such as the American Cancer Society (“I Can Cope” and “Make Today Count”) or the Leukemia and Lymphoma Society of America.

Health Care Resources

The patient with limited social support may need help at home until strength and energy return. A home care aide may suffice for some patients, whereas for others a visiting nurse may be needed to reinforce teaching. The patient may also need equipment for ADLs and ambulation. Assess financial resources. Cancer treatment is expensive, and you will need to coordinate with the social services department to ensure that insurance is adequate. If the patient is uninsured, explore other sources, such as drug company-sponsored

CHART 42-11 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Infection

- Avoid crowds and other gatherings of people who might be ill.
- Do not share personal toilet articles, such as toothbrushes, toothpaste, washcloths, or deodorant sticks, with others.
- If possible, bathe daily.
- Wash the armpits, groin, genitals, and anal area at least twice a day with an antimicrobial soap.
- Clean your toothbrush daily by either running it through the dishwasher or rinsing it in liquid laundry bleach and then rinsing it with running water.
- Wash your hands thoroughly with an antimicrobial soap before you eat or drink, after touching a pet, after shaking hands with anyone, as soon as you come home from any outing, and after using the toilet.
- Eat a low-bacteria diet, and avoid salads, raw fruits and vegetables, and undercooked meat.
- Wash dishes between uses with hot, sudsy water, or use a dishwasher.
- Do not drink water that has been standing for longer than 15 minutes.
- Do not reuse cups and glasses without washing.
- Avoid changing pet litter boxes. If unavoidable, use gloves or wash hands immediately.
- Avoid keeping turtles and reptiles as pets.
- Do not feed pets raw or undercooked meat.
- Take your temperature at least twice a day.
- Report any of these manifestations of infection to your physician immediately:
 - Temperature greater than 100° F (38° C)
 - Persistent cough (with or without sputum)
 - Pus or foul-smelling drainage from any open skin area or normal body opening
 - Presence of a boil or abscess
 - Urine that is cloudy or foul smelling, or burning on urination
- Take all drugs as prescribed.
- Do not dig in the garden or work with houseplants.
- Avoid travel to areas of the world with poor sanitation or inadequate health care facilities.

compassionate aid programs. The Leukemia and Lymphoma Society of America offers limited financial help, sponsors support groups, and provides information for patients and families.

Prolonged outpatient contact and follow-up are necessary, and patients need transportation to the outpatient facility. Many local units of the American Cancer Society offer free transportation to patients with cancer, including leukemia.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Six weeks after hematopoietic stem cell transplantation for leukemia, the client's white blood cell (WBC) count is 8200/mm³. What is the nurse's best action in view of this laboratory result?

- Notify the health care provider immediately.
- Assess the client for other symptoms of infection.
- Document the laboratory report as the only action.
- Remind the client to avoid crowds and people who are ill.

CHART 42-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

The Patient at Risk for Bleeding

- Use an electric shaver
- Use a soft-bristled toothbrush, and do not floss.
- Do not have dental work done without consulting your doctor.
- Do not take aspirin or any aspirin-containing products. Read the label to be sure the products do not contain aspirin or salicylates.
- Wear shoes or slippers with a sole to avoid foot injury.
- Do not participate in contact sports or any activity likely to result in your being bumped, scratched, or scraped.
- If you are bumped, apply ice to the site for at least 1 hour.
- Notify your physician if you:
 - Experience an injury and persistent bleeding results
 - Have excessive menstrual bleeding
 - See blood in your urine or bowel movement
 - Have a headache that does not respond to acetaminophen
- Avoid anal intercourse.
- Take a stool softener to prevent straining during a bowel movement.
- Do not use enemas or rectal suppositories.
- Avoid bending over at the waist.
- Do not wear clothing or shoes that are tight or that rub.
- Avoid blowing your nose or placing objects in your nose. If you must blow your nose, do so gently without blocking either nasal passage.

EVALUATION: OUTCOMES

Evaluate the care of the patient with leukemia based on the identified priority patient problems. The expected outcomes include that the patient will:

- Remain free of infection and sepsis
- Not experience episodes of bleeding
- Be able to balance activity and rest
- Use energy conservation techniques
- Adapt lifestyle to energy level

Specific indicators for these outcomes are listed for each priority patient problem in the Planning and Implementation section (see earlier).

MALIGNANT LYMPHOMAS

Lymphomas are cancers of the lymphoid tissues. They are the abnormal overgrowth of one type of leukocyte, the lymphocyte. They differ from leukemia in the degree of maturation of the affected cells and the location of cancer cell production. Lymphomas are cancers of committed lymphocytes rather than stem cell precursors (as in leukemia). This growth occurs in lymphoid tissues scattered throughout the body, especially the lymph nodes and spleen, rather than in the bone marrow. Lymphomas are solid tumors rather than cellular suspensions within the blood and bone marrow. There are two major categories of lymphoma among adults: Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL).

HODGKIN'S LYMPHOMA

Pathophysiology

Hodgkin's lymphoma (HL) is a cancer that can affect any age-group. However, it appears to peak in two different age

groups: (1) in teens and young adults, and (2) in adults in their 50s and 60s (McCance et al., 2010). HL affects younger men and women equally, but the disease is more prevalent in men in the older group.

The exact cause of HL is uncertain. Possible causes of HL include viral infections (i.e., Epstein-Barr virus [EBV], human T-cell leukemia/lymphoma virus [HTLV], and human immune deficiency virus [HIV]) and exposure to chemical agents. Most cases of the disease, however, occur in people without identifiable risk factors, and most people with presumptive risk factors do not get the disease.

This cancer usually starts in a single lymph node or a single chain of nodes. The tissue in the node becomes cancerous. These nodes contain a specific cancer cell type, the **Reed-Sternberg cell**, a marker for HL. HL generally spreads from one group of lymph nodes to the next in an orderly fashion, unlike non-Hodgkin's lymphoma.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The most common assessment finding is a large but painless lymph node or nodes. A distinctive rare finding in HL is pain in the lymph nodes that is brought on or made worse with ingestion of alcohol. The patient may also have constitutional symptoms, called "B symptoms," that may include fevers ($>101.5^{\circ}\text{F}$ [$>38.6^{\circ}\text{C}$]); drenching night sweats; and unexplained weight loss ($>10\%$ of normal body weight). These symptoms often mean a poorer prognosis. Many patients have no symptoms at time of diagnosis, and specific manifestations often depend on the site and extent of disease.

Diagnosis and subtype are established when biopsy of a node or mass reveals Reed-Sternberg cells (McCance et al., 2010). HL is then classified into one of several different subtypes on the basis of the World Health Organization (WHO) classification system.

After diagnosis, the next evaluation of the patient with HL is staging to determine the extent of disease. This process is detailed and must be accurate because the treatment regimen is determined by the extent of disease. Staging usually includes a history and physical examination, CBC, electrolyte panel, kidney and liver function tests, erythrocyte sedimentation rate (ESR), and a bone marrow aspiration and biopsy. Computed tomography (CT) of the neck, chest, abdomen, and pelvis is performed as part of the staging process. Positron emission tomography (PET) may be included to assess for areas of disease not detected by CT. PET scans are helpful after treatment to assess disease response to therapy. After staging procedures are complete, the stage of the disease is determined by the Ann Arbor Staging Criteria (Table 42-3).

INTERVENTIONS

Hodgkin's lymphoma (HL) is one of the most treatable types of cancer. Generally, for stage I and stage II disease, the treatment is external radiation of involved lymph node regions. With more extensive disease, radiation and combination chemotherapy are used to achieve remission. (See Chapter 24 on general care of patients receiving radiation and chemotherapy.)

TABLE 42-3 ANN ARBOR STAGING CRITERIA FOR HODGKIN'S LYMPHOMA

STAGE	MANIFESTATION CRITERIA
Ia	Disease is present only in a single lymph node region or in only one non-lymph node site.
Ib	Disease location is the same as Ia. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIa	Disease is present in two or more separate lymph node regions on the same side of the diaphragm or two in two non-lymph node sites on the same side of the diaphragm.
IIb	Disease location is the same as IIa. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIIa	Disease extends to lymph node regions on both sides of the diaphragm.
IIIb	Disease location is the same as IIIa. In addition, the patient has some or all of these manifestations: persistent fever, night sweats, weight loss of more than 10% of normal body weight.
IIIC	Same as IIIb along with disease present in the spleen.
IV	Disease is present in many body areas, including in one or more non-nodal tissues and organs.

Source: Carbone, P.P., Kaplan, H.S., Musshoff, K., Smithers, D.W., & Tubiana, M. (1971). Report of the committee on Hodgkin's disease staging classification. *Cancer Research* 31: 1860-1861.

Nursing management of the patient undergoing treatment for HL focuses on the acute side effects of therapy, especially:

- Drug-induced pancytopenia, which increases the risk for infection, anemia, and bleeding
- Severe nausea and vomiting, which impairs nutrition
- Skin problems at the site of radiation
- Constipation or diarrhea
- Impaired liver function either by metastasis to the liver or by chemotherapy drugs
- Permanent sterility for male patients receiving radiation to the abdominopelvic region in the pattern of an inverted Y in combination with specific chemotherapy drugs (The patient is informed of this side effect and given the option to store sperm in a sperm bank before treatment.)
- Secondary cancer development as a result of HL treatment (Long-term follow-up includes screening for recurrence, as well as the possible development of a secondary cancer.)

NON-HODGKIN'S LYMPHOMA

Pathophysiology

Non-Hodgkin's lymphoma (NHL) includes all lymphoid cancers that do not have the Reed-Sternberg cell. There are over 60 subtypes of NHL divided into either indolent or aggressive lymphomas. NHL generally spreads through the lymphatic system in a less orderly fashion than HL. It represents 4% of all cancer-related deaths in the United States, and about 63,000 new cases are diagnosed each year (*American Cancer Society, 2011*). The disease is more common in men and older adults.

The exact cause of NHL is unknown although both autoimmune disease and immunosuppressive disorders appear to be associated with an increased risk (e.g., solid organ transplantation, immunosuppressive drug therapy, infection with HIV). Chronic infection from *Helicobacter pylori* is associated with a type of lymphoma called *mucosa-associated lymphoid tissue (MALT) lymphoma*, and Epstein-Barr viral infection has been associated with Burkitt's lymphoma. NHL may be related to inherited gene damage. Gene damage may result in loss of suppressor gene function, allowing cancer development to occur. There is an increased incidence of NHL among people exposed to pesticides, insecticides, and dust.

Patients usually have swollen lymph nodes (lymphadenopathy) or tumor spread to other organs at the time of diagnosis. The most common extranodal sites are the GI tract, skin, bone marrow, sinuses, thyroid, or central nervous system (CNS). Enlarged lymph nodes may be the only symptom of lymphoma because these nodes can arise from lymphoid cells in any tissue and can spread to any organ. Painless swelling of the cervical, axillary, inguinal, and femoral nodes is most often seen. The diagnosis of NHL can be made only after the biopsy of an involved lymph node is reviewed by a hematopathologist.

Lymphoma is not a single disease but, rather, a group of diseases. The specific subtype of lymphoma must be classified because treatment decision varies depending on the subtype. Lymphomas are classified using the World Health Organization (WHO) classification system. The classification system is based on cytology, immunophenotyping by flow cytometry, and genetic (chromosomal translocations and molecular rearrangements) and clinical features. NHLs are broadly classified as B-cell or T-cell lymphomas, depending on the lymphocyte type that gave rise to the cancer. B-cell lymphomas are most common (about 90% of NHLs) (McNally, 2011).

Staging is more complicated than for Hodgkin's lymphoma and is based on the Revised European-American Lymphoma (REAL) classification system. In addition, lactate dehydrogenase (LDH) levels and beta-2 microglobulin levels are also evaluated to measure tumor growth rates and calculate prognosis. (High LDH levels and high beta-2 microglobulin levels are associated with a poorer prognosis.) Cerebrospinal fluid is evaluated when lymphoma is present in the CNS, around the spinal column, brain, or testes, and when HIV-related lymphoma is diagnosed.

Patients with **indolent** (slow-growing) lymphomas usually have painless lymph node swelling at diagnosis. Those with more aggressive B-cell lymphomas may have large abdominal or mediastinal masses at diagnosis that become symptomatic soon after they develop. Constitutional symptoms, also known as "B symptoms," such as fevers greater than 101.5° F (>38.6° C), drenching night sweats, and unintentional weight loss greater than 10% of body weight in the past 6 months, occur in about one third of patients with aggressive lymphomas and rarely in indolent lymphomas. Bone marrow involvement in indolent lymphomas is common.

PATIENT-CENTERED COLLABORATIVE CARE

Treatment options for patients with NHL vary based on several factors. These include the subtype of the tumor, international prognostic index (IPI) score, stage of the disease,

performance status, and overall tumor burden. Special consideration for patients with additional health problems is important, especially among older adult patients. Many new therapies have evolved over the past decade for various subtypes of NHL. These therapies include combinations of chemotherapy drugs alone or in combination with monoclonal antibodies (e.g., rituximab and alemtuzumab), localized radiation therapy, radiolabeled antibodies (^{131}I tositumomab and ^{90}Y ibritumomab tiuxetan), hematopoietic stem cell transplantation, and investigational agents, such as vaccine therapy or proteasome inhibitors (e.g., bortezomib) (Byar & Workman, 2012).

Nursing care needs are similar to those for patients with HL, with additional organ-specific problems if the disease is widespread. With the use of biotherapy for NHL, close monitoring for infusion-related reactions is needed during and after the delivery of monoclonal antibodies (see Chapter 24 for general care of patients undergoing treatment with biotherapy). Patient and family education are important in the management and prevention of complications.

MULTIPLE MYELOMA

Pathophysiology

Multiple myeloma is a white blood cell (WBC) cancer that involves a more mature lymphocyte called a *plasma cell*, which secretes antibodies. There is overgrowth of B-lymphocyte plasma cells in the bone marrow. When these cells become cancerous, they overproduce antibodies (gamma globulins). Thus the disorder is called a “gammopathy.” When the myeloma cells are overproduced, fewer functional red blood cells (RBCs), WBCs, and platelets are produced, leading to anemia and increased risk for infection and bleeding.

In addition to the excess antibodies, multiple myeloma cells also produce excess cytokines (see Chapter 19) that increase the cancer cell growth rates and destroy bone. The excess antibodies are released into the blood, increasing the serum protein levels and clogging blood vessels in the kidney and other organs. Without treatment, the disease causes progressive bone destruction, bleeding problems, kidney failure, immunosuppression, and death.

Multiple myeloma accounts for about 12,000 deaths per year in the United States (American Cancer Society, 2011). The disease is rare in people younger than 40 years, and most cases are diagnosed in people older than 65 years. The incidence is higher in American blacks than in whites, with a much higher incidence in men.

The cause of multiple myeloma is unknown. Possible risk factors include radiation exposure, chemical exposure, and infection with human herpes virus 8 (HHV-8). This cancer can be distinguished by changes in immunoglobulin structure that begin within a single clone of cells even before transformation to cancer occurs. When the specifically altered immunoglobulin is present in a high enough quantity, the type can be seen and recognized as a unique “spike” pattern on a serum electrophoresis test of plasma proteins. Because one clone of cells develops into cancer cells, the abnormal immunoglobulin produced by these cells is a *monoclonal* immunoglobulin. Most monoclonal immunoglobulins in myeloma are the immunoglobulin G (IgG) type of paraprotein (60%) or the immunoglobulin A (IgA) type of paraprotein (20%).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

About 20% of patients have no symptoms at time of the diagnosis. An elevation of serum total protein or a detection of a monoclonal protein (also known as *paraprotein*) in the blood or urine may be the only finding. Other possible manifestations include fatigue, anemia, bone pain, pathologic fractures, recurrent bacterial infections, and kidney dysfunction. Rare additional problems include hypercalcemia and hyperviscosity syndrome.

A positive finding of a serum monoclonal protein is not sufficient to make a diagnosis of multiple myeloma. About 1% of the population produce a monoclonal protein in the blood but do not have multiple myeloma. This condition is labeled *monoclonal gammopathy of undetermined significance* or *MGUS*, which is a premalignant condition. Patients with MGUS usually have a monoclonal protein concentration below 3 g/dL, less than 5% plasma cells in the bone marrow, absent or only a small amount monoclonal protein in the urine, and no bone lytic lesions, anemia, hypercalcemia, or kidney insufficiency. Follow-up of patients with MGUS is important because a small percentage eventually will develop multiple myeloma.

Multiple myeloma is distinguished from MGUS by having more than 10% of the bone marrow infiltrated with plasma cells, the presence of a monoclonal protein in the serum or urine, and the presence of osteolytic bone lesions.

The staging system for multiple myeloma divides patients into stages and prognostic groups on the basis of the serum beta-2 microglobulin and albumin levels. Other factors that help determine prognosis include age, performance status, serum creatinine, lactate dehydrogenase level (LDH), C-reactive protein, hemoglobin level, platelet count, and cytogenetic abnormalities found in the bone marrow biopsy.

The patient usually first notices fatigue, easy bruising, and bone pain. Symptoms, such as bone fractures, hypertension, infection, hypercalcemia, and fluid imbalance, may occur as the disease progresses. Diagnosis is made by x-ray findings of bone thinning with areas of bone loss that resemble Swiss cheese, high immunoglobulin and plasma protein levels, and the presence of Bence-Jones protein (protein composed of incomplete antibodies) in the urine. A bone marrow biopsy is performed to evaluate and diagnose the disease and also to determine chromosome abnormalities. An abnormality of chromosome 11 predicts a longer survival, and absence of chromosome 13 is a poor prognostic factor.

INTERVENTIONS

Treatment options vary. For minimal disease, watchful waiting may be an option instead of chemotherapy. Standard treatment for multiple myeloma is the use of novel agents such as bortezomib (Velcade), which is a proteasome inhibitor, and immunomodulating drugs such as thalidomide (Thalomid) and lenalidomide (Revlimid). These agents, which are types of targeted cancer therapy (see Chapter 24), may be used alone or in combination with steroids, such as dexamethasone (Decadron). Agents are selected based on whether the patient is eligible for an autologous stem cell transplant. If he or she is eligible, drug therapy is used to

reduce tumor burden before transplantation. For patients who are not eligible for an autologous stem cell transplantation because of age or other health problems, standard chemotherapy drugs such as melphalan, prednisone, vincristine, cyclophosphamide, doxorubicin, and carmustine are usually effective in controlling but not curing the disease.

Side effects and severe toxicities can occur with these newer agents (Bertolotti et al., 2008). Myelosuppression is an expected side effect of many myeloma therapies. A nursing priority is to teach the patient about the manifestations. The risk for thromboembolic events is increased with the use of thalidomide and lenalidomide. Peripheral neuropathy can be challenging, causing pain and poor quality of life. Gastrointestinal side effects, such as nausea, vomiting, diarrhea, and constipation, are severe and can be life threatening if not managed properly (Smith et al., 2008).

Despite therapy, multiple myeloma remains incurable. Most patients have local or generalized bone pain. Analgesics and alternative approaches for pain management, such as relaxation techniques, aromatherapy, or hypnosis, are used for pain relief. The bone disease of multiple myeloma is treated with bisphosphonates (pamidronate, zoledronic acid, ibandronate), which inhibit bone resorption and reduce skeletal complications (Miceli et al., 2011).

COAGULATION DISORDERS

Coagulation disorders are bleeding disorders with increased bleeding resulting from defects in one or more components regulating the blood clotting system. Bleeding disorders may be spontaneous or traumatic, localized or generalized, life-long or acquired. They can arise from a defect in the clotting processes at the vascular, platelet, or clotting factor level.

PLATELET DISORDERS

Platelets have a vital role in blood clotting. Blood clotting always starts with platelets sticking together (aggregation) and forming a platelet plug. Any condition that either reduces the number of platelets or interferes with their ability to adhere (stick to one another, blood vessel walls, collagen, or fibrin threads) can result in increased bleeding. Platelet disorders are inherited, acquired, or temporarily induced by drugs that limit platelet production or inhibit aggregation.

Platelet numbers below that needed for blood clotting is called **thrombocytopenia**. It may occur as a result of other conditions or treatments that suppress general bone marrow activity. The problem also can occur from limited platelet formation or an increased rate of platelet destruction in the spleen. The two thrombocytopenic conditions affecting adults are *autoimmune thrombocytopenic purpura* and *thrombotic thrombocytopenic purpura*.

AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Pathophysiology

Autoimmune thrombocytopenic purpura is also called *idiopathic thrombocytopenic purpura* (ITP). The total number of circulating platelets is greatly reduced in ITP, even though platelet production in the bone marrow is normal.

Patients with this disorder make an antibody against the surface of their own platelets (an antiplatelet antibody). This

antibody coats the surface of the platelets, making them more likely to be destroyed by macrophages (Hunt, 2010) (see Chapter 19). The spleen has many macrophages, and the blood vessels of the spleen are long and twisted. Both of these conditions cause destruction of antibody-coated platelets in the spleen. When platelet destruction exceeds platelet production, the number of circulating platelets decreases and blood clotting slows.

Although the cause of this disorder is autoimmune, the trigger for the production of autoantibodies is unknown but viral infection is suspected. ITP is most common among women between the ages of 20 and 40 years and among people who have other autoimmune disorders.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Manifestations of ITP are at first seen in the skin and mucous membranes: large **ecchymoses** (bruises) or a petechial rash on the arms, legs, upper chest, and neck. Mucosal bleeding occurs easily. If the patient has had significant blood loss, anemia may also be present.

A rare complication is intracranial bleeding-induced stroke. Assess for neurologic function and mental status (see Chapter 43). Ask family members whether the patient's behavior and responses are typical or represent a change.

ITP is diagnosed by a low platelet count and large numbers of megakaryocytes in the bone marrow. Antiplatelet antibodies may be detected in the blood, although this is not a specific test. If the patient has any episodes of bleeding, hematocrit and hemoglobin levels may be low.

INTERVENTIONS

As a result of the decreased platelet count, the patient is at great risk for bleeding. Interventions include therapy for the underlying condition and protection from trauma-induced bleeding episodes. Treatment is often limited to those patients with platelet counts lower than $50,000/\text{mm}^3$, those who are bleeding, and those who are at high risk for bleeding.

Drug therapy to control ITP includes drugs that suppress immune function to some degree. Drugs such as corticosteroids, azathioprine (Imuran), eltrombopag, rituximab (Rituxan), and romiplostim are used to inhibit immune system production of antiplatelet autoantibodies (Winkeljohn, 2010). IV immunoglobulin and IV anti-Rho can help prevent the destruction of antibody-coated platelets, although anti-Rho carries a Black Box Warning for increased risk for intravascular hemolysis and death. More aggressive therapy involves low doses of chemotherapy drugs.

Platelet transfusions are used when platelet counts are less than $20,000/\text{mm}^3$ and the patient has an acute life-threatening bleeding episode. Transfusions are not performed routinely because the donated platelets are just as rapidly destroyed by the spleen as the patient's own platelets. (See discussion on p. 900 in the **Platelet Transfusions** section.)

Maintaining a safe environment helps protect the patient from conditions that can lead to bleeding. Closely monitor the amount of bleeding that is occurring. (For nursing care actions, see the discussion of Minimizing Injury on p. 889 in the **Leukemia** section.)

Surgical management with a splenectomy may be needed for the patient who does not respond to drug therapy. (The spleen is the site of excessive platelet destruction.) After splenectomy, the patient is at increased risk for infection because the spleen performs many protective immune functions.

THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic thrombocytopenic purpura (TTP) is a rare disorder in which platelets clump together abnormally in the capillaries and too few platelets remain in circulation. The patient has inappropriate clotting, yet the blood fails to clot properly when trauma occurs. The cause of TTP appears to be an autoimmune reaction in blood vessel cells (endothelial cells) that makes platelets clump together in very small blood vessels. Tissues become ischemic, leading to kidney failure, myocardial infarction, and stroke. Untreated, this disorder is often fatal within 3 months.

Management of the patient with TTP focuses on preventing platelet clumping and stopping the underlying autoimmune process. Treatment consists of plasma pheresis and the infusion of fresh frozen plasma to provide platelet aggregation inhibitors. Drugs that inhibit platelet clumping, such as aspirin, alprostadil (Prostin), and plicamycin, also may be helpful. Immunosuppressive therapy reduces the intensity of this disorder.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client with autoimmune thrombocytopenic purpura who is receiving corticosteroid therapy to control the disease?

- A. "Avoid contact sports and any activity that could cause injury."
- B. "Report any rash to your health care provider immediately."
- C. "Be sure to drink at least 3 liters of water daily."
- D. "Take a low-dose aspirin daily with food."

CLOTTING FACTOR DISORDERS

Coagulation or bleeding disorders can result from a clotting factor defect. Defects include the inability to produce a specific clotting factor, production of low quantities of a clotting factor, or production of a less active form of a clotting factor.

Most clotting factor disorders are genetic problems of one clotting factor. Acquired clotting factor disorders usually are related to a damaged liver that cannot produce proper amounts of clotting factors. Common disorders that result from defects at the clotting factor level include hemophilias A and B and von Willebrand's disease. Disseminated intravascular coagulation (DIC) often occurs with septic shock (see Chapter 39).

HEMOPHILIA

Pathophysiology and Genetics of the Disorder

Hemophilia is actually two different hereditary bleeding disorders resulting from clotting factor deficiencies. Hemophilia A (classic hemophilia) is a deficiency of factor VIII and accounts for 80% of cases of hemophilia. Hemophilia B (Christmas disease) is a deficiency of factor IX and accounts for 20% of cases. The incidence of both disorders is 1 in 10,000 (McCance et al., 2010).

GENETIC/GENOMIC CONSIDERATIONS

Hemophilia is an X-linked recessive trait. Women who are **carriers** (can pass on the gene without actually having the disorder) have a 50% chance of passing the hemophilia gene to their daughters (who then are carriers) and to their sons (who then have hemophilia). Hemophilia A affects mostly males, none of whose sons will have the gene for hemophilia and all of whose daughters will be carriers. About 30% of patients with hemophilia have no family history. It is thought that their disease is the result of a new gene mutation.

The clinical pictures of hemophilias A and B are identical. The patient has abnormal bleeding in response to any trauma because of a deficiency of the specific clotting factor. Patients with hemophilia do not bleed more often or even more rapidly than those without the disease, but they do bleed for a longer period. Hemophiliacs form platelet plugs at the bleeding site, but the clotting factor deficiency impairs the formation of stable fibrin clots. This allows excessive bleeding, which may be mild, moderate, or severe, depending on the degree of factor deficiency.

PATIENT-CENTERED COLLABORATIVE CARE

Assessment of the patient with hemophilia shows:

- Excessive bleeding from minor cuts, bruises, or abrasions (from abnormal platelet function)
- Joint and muscle hemorrhages that lead to disabling long-term problems and may require joint replacement
- A tendency to bruise easily
- Prolonged and potentially fatal hemorrhage after surgery

The laboratory test results for a patient with hemophilia show a prolonged partial thromboplastin time (PTT), a normal bleeding time, and a normal prothrombin time (PT). The most common problem that occurs with hemophilia is degenerating joint function as a result of chronic bleeding into the joints, especially the hip and knee.

The bleeding problems of hemophilia A are managed by either regularly scheduled infusions of synthetic factor VIII or factor VIII cryoprecipitate or intermittent infusions as needed (see [Cryoprecipitate Transfusions](#) section, p. 900). The cost of factor VIII replacement is prohibitive for many people with hemophilia. The source of factor VIII varies ([Table 42-4](#)). New sources include recombinant DNA technology produced synthetic drug. Traditional sources are derived from pooled human serum that is purified to varying degrees and some animal sources. Those precipitated clotting factors derived from pooled human serum do have some risk for viral contamination, even with the use of many techniques to purify the drug ([National Hemophilia Foundation, 2010](#)). Infectious complications of hemophilia therapy include hepatitis B, hepatitis C, cytomegalovirus, and HIV.

HEPARIN-INDUCED THROMBOCYTOPENIA

Heparin-induced thrombocytopenia (HIT) is a serious immune-mediated clotting disorder that features an unexplained drop in platelet count after heparin treatment with or without thrombotic complications. The occurrence is increasing because of the increased use of heparin. Unlike

other clotting disorders, HIT is an immune-mediated drug reaction that is caused by heparin-dependent platelet-activating immunoglobulin G (IgG) antibodies in which heparin binds with platelet factor 4 (PF4). This drug binding leads to the development of a highly reactive immune complex that activates the platelets. Once activated, platelets release procoagulants and PF4, which neutralizes heparin and increases thrombin generation from prothrombin.

HIT can occur in patients receiving any type of heparin, including unfractionated heparin and low-molecular-weight heparin, although it is more common after exposure to unfractionated heparin (Glass & Spitrey, 2009). The incidence is higher among patients with risk factors that include (1) duration of heparin use longer than 1 week, (2) exposure to unfractionated heparin, (3) postsurgical thromboprophylaxis, and (4) being female.

Manifestations of HIT include venous thrombotic complications such as deep vein thrombosis (50%) and pulmonary embolism (25%). The diagnosis is based on the patient's exposure to heparin, which can be up to 100 days before the event. Thrombocytopenia after heparin exposure is the hallmark sign of HIT. Clinical, as well as laboratory, findings need to be interpreted to properly diagnose this disorder.

Once HIT is diagnosed, anticoagulation therapy is started. Drugs approved for HIT management are argatroban (Argatroban), lepirudin (Refludan), and bivalirudin (Angiomax) (Sparks, 2009).

TRANSFUSION THERAPY

Any blood component may be removed from a donor and transfused to a recipient (Leighton, 2008). More than 98% of the blood supply in the United States comes from volunteer donors. Blood components may be transfused individually or collectively, with varying degrees of benefit to the recipient. Table 42-5 lists indications for transfusion therapy.

PRETRANSFUSION RESPONSIBILITIES

Nursing actions during transfusions aim at prevention or early recognition of adverse transfusion reactions. Preparation of the patient for transfusion therapy is critical, and institutional blood product administration procedures must be carefully followed. Before administering any blood product, review the agency's policies and procedures. Chart 42-13 lists best practices for transfusion therapy.

A prescription from the health care provider is required to administer blood or its components. The prescription specifies the type of component, the volume, and any special conditions the physician judges to be important. Verify the prescription for accuracy and completeness. In many hospitals, a separate consent form must be obtained before a transfusion is performed.

A blood specimen is obtained for crossmatching (testing of the donor's blood and the recipient's blood for compatibility). The procedure and responsibility for obtaining this specimen are specified by hospital policy. The laboratory requires at least 45 minutes to complete the crossmatch testing. Usually, a new crossmatching specimen is required at least every 72 hours.

TABLE 42-4 ANTIHEMOPHILIC DRUGS

DRUG TYPES	SOURCES
High purity antihemophilic factor - Alphanate - Humate-P - Koate-DIV	Pooled human serum
Monoclonal antibody purified antihemophilic factor - Hemofil-M - Monarc-M - Monoclata-P	Pooled human serum
Recombinant antihemophilic factor - Helixate FS - Kogenate FS - Recombinate	Recombinant DNA technology
B-domain deleted (BDD) recombinant antihemophilic factor ReFacto	Recombinant DNA technology
Recombinant antihemophilic factor plasma/albumin-free method (rAHF-PFM) Advate	Recombinant DNA technology
Recombinant antihemophilic factor plasma/albumin-free method Xyntha	Recombinant DNA technology
Porcine factor VIII Hyate: C	Animal serum

TABLE 42-5 INDICATIONS FOR TREATMENT WITH BLOOD COMPONENTS

COMPONENT	VOLUME	INFUSION TIME	INDICATIONS
Packed red blood cells (PRBCs)	200-250 mL	2-4 hr	Anemia; hemoglobin <6 g/dL, 6-10 g/dL, depending on symptoms
Washed red blood cells (WBC-poor PRBCs)	200 mL	2-4 hr	History of allergic transfusion reactions Hematopoietic stem cell transplant patients
Platelets			
Pooled	About 300 mL	15-30 min	Thrombocytopenia, platelet count <20,000 Patients who are actively bleeding with a platelet count <50,000
Single donor	200 mL	30 min	History of febrile or allergic reactions
Fresh frozen plasma	200 mL	15-30 min	Deficiency in plasma coagulation factors Prothrombin or partial thromboplastin time 1.5 times normal
Cryoprecipitate	10-20 mL/ unit	15-30 min	Hemophilia VIII or von Willebrand's disease Fibrinogen levels <100 mg/dL
White blood cells (WBCs)	400 mL	1 hr	Sepsis, neutropenic infection not responding to antibiotic therapy

CHART 42-13 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Transfusion Therapy

NURSING ACTIONS	RATIONALES
Before Infusion 1. Assess laboratory values. 2. Verify the medical prescription. 3. Assess the patient's vital signs, urine output, skin color, and history of transfusion reactions. 4. Obtain venous access. Use a central catheter or at least a 20-gauge needle if possible. 5. Obtain blood products from a blood bank. Transfuse as soon as possible after first performing all the required safety checks. 6. With another registered nurse, verify the patient by name and number, check blood compatibility, and note expiration time.	Many institutions have specific guidelines for blood product transfusions (e.g., platelet count <20,000 or hemoglobin <6 g/dL). Legally, a physician's prescription is required for transfusions. The prescription should state the type of product, dose, and transfusion time. Determine whether the patient can tolerate infusion. Baseline information may be needed to help identify transfusion reactions. The larger-bore needle allows cells to flow more easily without occluding the lumen of the catheter. Once a blood product has been released from the blood bank, the product should be transfused as soon as possible (e.g., red blood cell transfusions should be completed within 4 hours of removal from refrigeration). Human error is the most common cause of ABO incompatibility reactions.
During Infusion 7. Administer the blood product using the appropriate filtered tubing. 8. Dilute blood products with only normal saline solution. 9. Remain with the patient during the first 15 to 30 minutes of the infusion. 10. Infuse the blood product at the prescribed rate. 11. Monitor vital signs.	Filters are needed to remove aggregates and possible contaminants. Hemolysis occurs if any other IV solution is used. Hemolytic reactions occur most often within the first 50 mL of the infusion. Fluid overload is a potential complication of rapid infusion. Vital sign changes often indicate transfusion reactions.
After Infusion 12. When the transfusion is completed, discontinue infusion and dispose of the bag and tubing properly. 13. Document.	Bloodborne pathogens may be spread inadvertently through improper disposal. The patient record should indicate the type of product infused, product number, volume infused, time of infusion, and any adverse reactions.

Blood components are viscous (thick), requiring that a larger needle (at least 20-gauge) be used, whenever possible, for venous access. Both Y tubing and straight tubing sets are used for blood component infusion (Fig. 42-7). A blood filter (about 170 μm) to remove sediment from the stored blood products is included with blood administration sets and must be used to transfuse most blood products. In massive transfusion, a microaggregate filter (20 to 42 μm) may be used.

Use normal saline as the solution to administer with blood products (Bielefeldt & DeWitt, 2009). Ringer's lactate and dextrose in water are not used for infusion with blood products because they cause clotting or hemolysis of blood cells.

! NURSING SAFETY PRIORITY**Action Alert**

Never add to or infuse other drugs with blood products because they may clot the blood during transfusion.

Before the transfusion, and in compliance with recommendations by The Joint Commission's National Patient Safety Goals (NPSG), the priority action is to determine that the blood component delivered is correct and that identification of the patient is correct (The Joint Commission [TJC], 2010). Check

the physician's prescription together with another registered nurse to determine the patient's identity and whether the hospital identification band name and number are identical to those on the blood component tag. According to The Joint Commission's National Patient Safety Goals, *the patient's room number is not an acceptable form of identification*. Some facilities use a bar code–point of care (BC-POC) system to improve patient safety and reduce identification errors (Dohnalek, 2007).

! NURSING SAFETY PRIORITY**Action Alert**

The nurse who will be actually administering the blood products must be one of the two professionals comparing the patient's identification with the information on the blood component bag.

Examine the blood bag label, the attached tag, and the requisition slip to ensure that the ABO and Rh types are compatible. Check the expiration date, because infusing older blood increases the risk for transfusion complications (Collins, 2011). Inspect the product for discoloration, gas bubbles, or cloudiness, all of which are indicators of bacterial growth or hemolysis.

FIG. 42-7 Blood administration setup.

TRANSFUSION RESPONSIBILITIES

Before starting the transfusion, explain the procedure to the patient. Assess vital signs, including temperature, immediately before starting the transfusion. Begin the infusion slowly. *Remain with the patient for the first 15 to 30 minutes.* Any severe reaction usually occurs with infusion of the first 50 mL of blood. Ask the patient to report unusual sensations such as chills, shortness of breath, hives, or itching. Assess vital signs 15 minutes after starting the transfusion to detect signs of a reaction. If there are none, the infusion rate can be increased to transfuse 1 unit in about 2 hours (depending on the patient's cardiac status and the facility's policy for rate of administration). Take vital signs at least every hour throughout the transfusion or as specified by agency policy.

Blood components without large amounts of RBCs can be infused more quickly. The identification checks are the same as for RBC transfusions. It may be necessary to infuse blood products at a slower rate for older patients. Best practices related to the nursing care needs of older patients during transfusion therapy are listed in [Chart 42-14](#).

Electrolyte imbalances are possible as a result of transfusions, especially with packed red blood cells or with whole blood. Potassium is the main electrolyte inside cells. During transfusions, some cells are damaged, releasing potassium and raising the patient's serum potassium level above normal ([hyperkalemia](#)). This problem is more likely when the blood being transfused has been frozen or is several weeks old.

CHART 42-14 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Older Adult Receiving a Transfusion

- Assess the patient's circulatory, kidney, and fluid status before initiating the transfusion.
- Use no larger than a 19-gauge needle.
- Try to use blood that is less than 1 week old. (Older blood cell membranes are more fragile, break easily, and release potassium into the circulation.)
- Take vital signs (especially pulse, blood pressure, and respiratory rate) every 15 minutes throughout the transfusion. Changes in these parameters can indicate fluid overload and may also be the only indicators of adverse transfusion reactions.
 - Overload
 - Rapid bounding pulse
 - Hypertension
 - Swollen superficial veins
 - Transfusion Reaction
 - Rapid thready pulse
 - Hypotension
 - Increased pallor, cyanosis
- Administer blood slowly, taking 2 to 4 hours for each unit of whole blood, packed red blood cells, or plasma.
- Avoid concurrent fluid administration into any other IV site.
- If possible, allow 2 full hours after the administration of 1 unit of blood before administering the next unit.

TABLE 42-6 COMPATIBILITY CHART FOR RED BLOOD CELL TRANSFUSIONS

DONOR	RECIPIENT			
	A	B	AB	O
A	X		X	
B		X	X	
AB			X	
O	X	X	X	X

TYPES OF TRANSFUSIONS

Red Blood Cell Transfusions

RBCs are given to replace cells lost as a result of trauma or surgery. Patients with problems that destroy RBCs or impair RBC maturation also may benefit from RBC transfusions. Packed RBCs, supplied in 250-mL bags, are a concentrated source of RBCs and are the most common component given to RBC-deficient patients. This type of blood product is used for patients who have a hemoglobin level less than 8 g/dL or who are hypoxemic or otherwise symptomatic.

Blood transfusions are actually transplantations of tissue from one person to another. The donor and recipient blood must thus be carefully checked for compatibility to prevent lethal reactions ([Table 42-6](#)). Compatibility is determined by two different antigen systems (cell surface proteins): the ABO system antigens and the Rh antigen, present on the membranes of RBCs.

RBC antigens are inherited. For the ABO system, a person inherits one of these:

- A antigen (type A blood)
- B antigen (type B blood)
- Both A and B antigens (type AB blood)
- Neither A nor B antigens (type O blood)

Within the first few years of life, circulating antibodies develop against the blood type antigens that person did not inherit. For example, a person with type A blood forms antibodies against type B blood. A person with type O blood has not inherited either A or B antigens and will form antibodies against RBCs with either A or B antigens. If RBCs that have an antigen are infused into a recipient who does not share that antigen, the infused blood is recognized by the recipient's antibodies as non-self and the recipient then has a reaction to the transfused products.

The Rh antigen system is slightly different. An Rh-negative person is born without the Rh-antigen on his or her RBCs and does not form antibodies unless he or she is specifically sensitized to it. Sensitization can occur with RBC transfusions from an Rh-positive person or from exposure during pregnancy and birth. Once an Rh-negative person has been sensitized and antibody development has occurred, any exposure to Rh-positive blood can cause a transfusion reaction. Antibody development can be prevented by giving anti-Rh-immunoglobulin as soon as exposure to the Rh antigen is suspected. *People who have Rh-positive blood can receive an RBC transfusion from an Rh-negative donor, but Rh-negative people should not receive Rh-positive blood.*

Platelet Transfusions

Platelets are given to patients with platelet counts below 10,000/mm³ and to patients with thrombocytopenia who are actively bleeding or are scheduled for an invasive procedure. Platelet transfusions are usually pooled from as many as 10 donors and do not have to be of the same blood type as the patient has. For patients who are going to receive a hematopoietic stem cell transplantation (HSCT) or who need multiple platelet transfusions, single-donor platelets may be prescribed. Single-donor platelets are taken from just one donor and decrease the amount of antigen exposure to the recipient, helping prevent the formation of platelet antibodies. The chances of allergic reactions to future platelet transfusions are thus reduced.

Platelet infusion bags usually contain 300 mL for pooled platelets and 200 mL for single-donor platelets. Platelets are fragile and must be infused immediately after being brought to the patient's room, usually over a 15- to 30-minute period. A special transfusion set with a smaller filter and shorter tubing is used. Additional platelet filters help remove white blood cells (WBCs) from the platelet concentrate. These filters are connected directly to the platelet transfusion set and are used for patients who have a history of febrile reactions or who need multiple platelet transfusions.

NURSING SAFETY PRIORITY

Action Alert

When infusing platelets, do not use the standard blood administration set because the filter traps the platelets and the longer tubing increases platelet adherence to the lumen.

Take the vital signs before the infusion, 15 minutes after the infusion starts, and at its completion. A patient who has had a transfusion reaction in the past may be given diphenhydramine (Benadryl) and acetaminophen (Tylenol) before the transfusion to reduce the chances of a reaction. He or she

can become febrile and have **rigors** (severe chills) during transfusion, but these symptoms are not a true transfusion reaction.

Plasma Transfusions

Plasma infusions may be given fresh to replace blood volume. More commonly, plasma is frozen immediately after donation, forming **fresh frozen plasma (FFP)**. Freezing preserves the clotting factors, and the plasma can then be used for patients with clotting disorders. Infuse FFP immediately after thawing while the clotting factors are still active. Patients who are actively bleeding with a prothrombin time (PT) or partial thromboplastin time (PTT) greater than 1.5 times normal are candidates for an FFP infusion.

ABO compatibility is required for transfusion of plasma products. The infusion bag contains about 200 mL. Infuse FFP as rapidly as the patient can tolerate, generally over a 30- to 60-minute period, through a regular Y set or straight filtered tubing.

Cryoprecipitate Transfusions

Cryoprecipitate is a product derived from plasma. Clotting factors VIII and XIII, von Willebrand's factor, and fibrinogen are precipitated from pooled plasma to produce cryoprecipitate (Cook, 2009). Patients with a fibrinogen level of less than 100 mg/dL are candidates for a cryoprecipitate infusion. Give this highly concentrated blood product to patients with clotting factor disorders at a volume of 10 to 15 mL/unit. Although cryoprecipitate can be infused, it is usually given by IV push within 3 minutes. Dosages are individualized, and it is best if the cryoprecipitate is ABO compatible.

Granulocyte (White Blood Cell) Transfusions

Rarely, neutropenic patients with infections receive white blood cell (WBC) replacement transfusions. This practice is less common as a result of the availability of WBC growth factors (Cook, 2009). WBC surfaces have many antigens that can cause severe reactions.

WBCs are suspended in 400 mL of plasma and should be infused slowly, usually over a 45- to 60-minute period depending on the concentration of cells being infused. Agency policies often require stricter monitoring of patients receiving WBCs because reactions are more common. A physician may need to be present in the hospital unit, and vital signs may need to be taken every 15 minutes throughout the transfusion. Amphotericin B infusion and WBC transfusions should be separated by 4 to 6 hours. The reasons for this are (1) the drug can bind to the membranes of the WBCs and destroy them, and (2) the drug induces fevers and chills, which would be difficult to differentiate from a transfusion reaction.

ACUTE TRANSFUSION REACTIONS

Patients can develop any of these transfusion reactions: febrile, hemolytic, allergic, or bacterial reactions; circulatory overload; or transfusion-associated graft-versus-host disease (GVHD). To prevent complications, remain alert during transfusions to detect early reactions and initiate appropriate treatment.

Febrile transfusion reactions occur most often in the patient with anti-WBC antibodies, a situation that can develop after

multiple transfusions, WBC transfusions, and platelet transfusions. The recipient develops chills, tachycardia, fever, hypotension, and tachypnea. Giving leukocyte-reduced blood or single-donor HLA-matched platelets reduces the risk for this type of reaction. WBC filters may be used to trap WBCs and prevent their infusion into the patient.

Hemolytic transfusion reactions are caused by blood type or Rh incompatibility. When blood containing antigens different from the patient's own antigens is infused, antigen-antibody complexes are formed in his or her blood. These complexes destroy the transfused cells and start inflammatory responses in the blood vessel walls and organs. The reaction may be mild, with fever and chills, or life threatening, with disseminated intravascular coagulation (DIC) and circulatory collapse (Katz, 2009). Other manifestations include:

- Apprehension
- Headache
- Chest pain
- Low back pain
- Tachycardia
- Tachypnea
- Hypotension
- Hemoglobinuria
- A sense of impending doom

The onset of a hemolytic reaction may be immediate or may not occur until subsequent units have been transfused.

Allergic transfusion reactions (also known as *anaphylactic transfusion reactions*) are most often seen in patients with a history of allergy. They may have urticaria, itching, bronchospasm, or anaphylaxis (Huntley, 2009). Onset of this type of reaction usually occurs during or up to 24 hours after the transfusion. Patients with a history of allergy can be given leukocyte-reduced or washed RBCs in which the WBCs, plasma, and immunoglobulin A have been removed. This procedure reduces the possibility of an allergic reaction.

Bacterial transfusion reactions occur as a result of infusion of contaminated blood products. Usually a gram-negative organism is the source because these bacteria grow rapidly in blood stored under refrigeration. Symptoms include tachycardia, hypotension, fever, chills, and shock (Katz, 2009). The onset of a bacterial transfusion reaction is rapid. (See Chapter 39 for care of the patient with septic shock.)

Circulatory overload can occur when a blood product is infused too quickly. This complication is most common with whole-blood transfusions or when the patient receives multiple transfusions. Older adults are most at risk for this problem (see Chart 42-14). Symptoms include:

- Hypertension
- Bounding pulse
- Distended jugular veins
- Dyspnea
- Restlessness
- Confusion

You can both manage and prevent this complication by monitoring intake and output, infusing blood products more slowly, and giving diuretics. (See Chapter 13 for management of patients with fluid overload.)

Transfusion-associated graft-versus-host disease (TA-GVHD) is a rare but life-threatening problem that can occur in both immunosuppressed and immunocompetent patients. Its cause in immunosuppressed patients is similar to that of

GVHD that occurs with allogeneic stem cell transplantation, discussed on pp. 888-889, in which donor T-cell lymphocytes attack host tissues.

Manifestations usually occur within 1 to 2 weeks and include thrombocytopenia, anorexia, nausea, vomiting, chronic hepatitis, weight loss, and recurrent infection.

TA-GVHD has an 80% to 90% mortality rate but can be prevented by using irradiated blood products. Irradiation reduces T-cells and their cytokine products.

AUTOLOGOUS BLOOD TRANSFUSIONS

Autologous blood transfusions involve collection and infusion of the patient's own blood. This type of transfusion eliminates compatibility problems and reduces the risk for transmitting bloodborne diseases. The four types of autologous blood transfusions are preoperative autologous blood donation, acute normovolemic hemodilution, intraoperative autologous transfusion, and postoperative blood salvage.

Autologous blood donation before surgery is a common type of autologous blood transfusion and involves collecting whole blood from the patient, dividing it into components, and storing it for later use after a scheduled surgical procedure. As long as hematocrit and hemoglobin levels are within a safe range, the patient can donate blood on a weekly basis until the prescribed amount of blood is obtained. Fresh packed RBCs may be stored for 40 days. For patients with rare blood types, blood may be frozen for up to 10 years. Autologous blood donation may not be used with some hematologic problems, some cardiac problems, and bacteremia.

Acute normovolemic hemodilution involves withdrawal of a patient's RBCs and volume replacement just before a surgical procedure. The goal is to decrease RBC loss during surgery. The blood is stored at room temperature for up to 6 hours and reinfused after surgery. This type of autologous transfusion is not used with anemic patients or those with poor kidney function.

Intraoperative autologous transfusion and blood salvage after surgery are the recovery and reinfusion of a patient's own blood from an operative field or from a bleeding wound. Special devices collect, filter, and drain the blood into a transfusion bag. This blood is used for trauma or surgical patients with severe blood loss. The salvaged blood must be reinfused within 6 hours.

Transfuse autologous blood products using the guidelines previously described. Although the patient receiving autologous blood is not at risk for most types of transfusion reactions, circulatory overload or bacterial transfusion reactions can still occur.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

Which assessment is most important for the nurse to perform for the client receiving one unit of packed red blood cells from an autologous donation?

- A. Temperature
- B. Blood pressure
- C. Oxygen saturation
- D. IV site for hives

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate oxygenation as a result of hematologic problems?

- Skin cyanosis or pallor (in lighter-skinned patients)
- Cyanosis or pallor of the lips and oral mucous membranes (in patients of any skin color)
- Tachycardia
- Tachypnea and dyspnea
- Slow capillary refill
- Cool to cold extremities
- Change in cognition, acute confusion
- Decreased oxygen saturation by pulse oximetry
- Decreased urine output
- Presence of bruises or petechiae
- Bleeding of the gums, around IV sites, at sites of venipuncture

What should you INTERPRET and how should you RESPOND to this patient experiencing inadequate oxygenation as a result of a hematologic problem?

Perform and interpret physical assessment, including:

- Taking vital signs
- Monitoring oxygen saturation by pulse oximetry
- Checking for blood in stool, urine, emesis
- Checking for bleeding in the mouth, around IV sites, drains, urinary catheters

- Checking most recent laboratory values for hematocrit and hemoglobin levels and platelet and RBC counts
- Assessing cognition (Mini-Mental State Examination [MMSE])

Respond by:

- Applying oxygen
- Keeping the patient's head elevated to about 30 degrees
- Handling the patient gently
- Keeping the patient warm (blankets)
- Applying firm pressure to areas actively bleeding
- Notifying physician or Rapid Response Team
- Instituting Bleeding Precautions
- Maintaining or initiating IV therapy
- Preparing to administer blood or blood products
- Keeping venipunctures to a minimum
- Prioritizing and pacing activities to prevent fatigue

On what should you REFLECT?

- Observe patient for evidence of restored tissue perfusion (see [Chapter 41](#)).
- Think about what may have precipitated this episode and what steps could be taken to either prevent a similar episode or identify it earlier.
- Think about what additional resources could improve the nursing response to this situation.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use aseptic technique during all central line dressing changes or any invasive procedure.
- Use Standard Precautions for all patients.
- Use good handwashing techniques before providing any care to a patient who is either immunocompromised or immune deficient.
- Use Bleeding Precautions for any patient with thrombocytopenia or pancytopenia (see [Chart 42-8](#)).
- Verify with another registered nurse prescriptions for transfusion of blood products.
- Use at least two forms of identification for the patient who is to receive a blood product transfusion (name and identification number).

Health Promotion and Maintenance

- Teach people to avoid unnecessary contact with environmental chemicals or toxins. If contact cannot be avoided, teach people to use safety precautions.

- Teach patients with sickle cell disease to avoid known conditions that trigger crises.
- Identify patients at high risk for infection because of disease or therapy.
- Teach the patient and family about the manifestations of infection and when to seek medical advice.
- Instruct patients who have anemia as a result of dietary deficiency which foods are good sources of iron, folic acid, and vitamin B₁₂.
- Teach precautions to take to avoid injury (see [Chart 42-12](#)) to patients at risk for bleeding.

Psychosocial Integrity

- Allow the patient the opportunity to express his or her feelings regarding the diagnosis of leukemia or lymphoma or the treatment regimen.
- Explain all procedures, restrictions, drugs, and follow-up care to the patient and family.
- Offer alternative therapies for relaxation, pain reduction, and distraction, such as massage, music therapy, and guided imagery.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Refer patients and family members to local cancer resources and support groups.
- Reassure patients having pain that using opioid analgesics for needed pain relief is not drug abuse.

Physiological Integrity

- Teach the patient about any drugs to be continued after discharge from the hospital.
- Instruct the patient and family in the manifestations of complications and when to seek assistance.
- Pace nonurgent health care activities to reduce the risk for fatigue among patients with anemia or pancytopenia.
- Assess patients in the induction phase of chemotherapy and those after BMT every 8 hours for manifestations of infection.
- Assess the skin integrity of the perianal region of a patient with leukemia after every bowel movement.
- Administer analgesics on a schedule rather than PRN.
- Use normal saline as the solution infusing with blood products.
- Transfuse blood products more slowly to older patients or those who have a cardiac problem.
- Remain with the patient during the first 15 minutes of infusion of any blood product.
- Do not administer any drugs with infusing blood products.

CONCEPT OVERVIEW

Mobility, Sensation, and Cognition

The term *mobility* means movement. When referring to physical mobility, it means the ability of the body to move. Mobility is needed for ADL performance and many body functions, including digestion, elimination, circulation, and muscle integrity. In some cases, it helps keep a person *safe* by being able to move to prevent injury.

Mobility is accomplished primarily through the integration of the neurologic and musculoskeletal body systems. Adequate energy from food is needed to nourish the cells of these systems to promote proper function and energy.

Sensation refers to receiving sensory input from the cells of the skin (feeling), eyes (seeing), and ears (hearing) and accurately interpreting this input in the neurons of the central nervous system (CNS). Therefore sensation is also needed to keep the body *safe*. For example, if a person cannot feel water temperature, a burn may result. If vision is impaired, a fall may occur.

Cognition refers to mental processes and intellectual function and is controlled by certain neurons in the gray matter of the brain. These cells are very sensitive to serum glucose and oxygen levels. If either of these substances falls below the amounts needed, the cells cannot function properly, resulting in diminished cognitive ability and a decreased level of consciousness.

Appropriate judgment and decision making are needed to keep a person *safe*. These cognitive processes also allow a person to perform day-to-day activities such as knowing when to eat or how to drive a car.

One or all of these three human needs may be unmet as a result of disease, injury, surgery, or drugs. Problems of the neurologic, sensory, and musculoskeletal systems most commonly affect the need for mobility, sensation, and cognition. The interrelationship of these needs can be compared to a computer and its parts.

As seen in Fig. 1, the computer's central processing unit (CPU), or processor, is the brain of the machine (the *cognitive center*). Much like the spinal cord, it works with the motherboard to send and receive messages (input and output). The connected pins and wires function like the spinal nerves. Peripherals such as the mouse and keyboard are similar in function to the peripheral nervous system (PNS) (*sensation*) and musculoskeletal system (*mobility*). When all of these parts are working properly, the computer functions without any problems.

FIG. 1

However, when the CPU (brain) does not work properly (decreased cognition), the motherboard (spinal cord) and/or peripherals (PNS and muscles) may not function as they should (decreased mobility and sensation). If the motherboard (spinal cord) is broken, no information is sent to or from any of the other parts of the computer. In both cases, there is no display on the monitor (Fig. 2).

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Determine a patient's allergy to iodine-based contrast media before diagnostic testing.

Health Promotion and Maintenance

2. Identify factors that place patients at risk for neurologic health problems.
3. Explain pre-test and post-test care associated with neurologic diagnostic testing.

Psychosocial Integrity

4. Explain psychological responses to neurologic health problems.

Physiological Integrity

5. Briefly review the anatomy and physiology of the nervous system.
6. Describe common physiologic changes associated with aging that affect the nervous system.
7. Interpret findings from a comprehensive neurologic physical assessment.
8. Identify how to perform a rapid neurologic assessment and interpret findings.
9. Assess patients for complications of neurologic diagnostic tests.

The nervous system controls *mobility, sensation, and cognition*. In addition, through the autonomic nervous system (ANS), it innervates many other body systems to make them function. For example, the sacral spinal nerves (part of the ANS) stimulate the detrusor muscle to contract when the urinary bladder is full.

Health problems involving trauma and diseases of the brain can impair the human needs for mobility, sensation, and/or cognition. When the spine or peripheral nervous system is affected, mobility and/or sensation is often impaired. The primary role of the nurse is to help restore these human needs or to assist the patient to adapt to their deficits.

ANATOMY AND PHYSIOLOGY REVIEW

The major divisions of the nervous system are the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS is composed of the brain and the spinal cord. The brain is contained within the cranium; the brain's role is to direct the regulation and function of the nervous system and other systems of the body. The spinal cord is lodged in the vertebral canal. From the brain, the spinal cord descends down the middle of the back and is surrounded and protected by the bony vertebral column. The spinal cord is surrounded by a clear fluid called *cerebrospinal fluid (CSF)* that protects the delicate nerve tissues against damage from banging against the inside of the vertebrae.

The PNS is composed of 12 pairs of cranial nerves, 31 pairs of spinal nerves, and the autonomic nervous system. The autonomic nervous system is further subdivided into sympathetic and parasympathetic fibers.

The nervous system contains two types of cells: neurons, which transmit or conduct nerve impulses; and neuroglial cells, which have an interdependent role with the neuron.

Nervous System Cells: Structure and Function

Neurons

The basic unit of the nervous system, the neuron, transmits impulses, or “messages.” Some neurons are **motor** (causing movement or mobility), and some are **sensory** (causing sensation). Some process information, and some retain information. When a neuron receives an impulse from another neuron, the effect may be excitation or inhibition. Each neuron has a *cell body*, or *soma*; short, branching processes called *dendrites*; and a single *axon* (Fig. 43-1).

Afferent neurons, also known as *sensory neurons*, are specialized to send impulses toward the CNS, away from the PNS. *Efferent* neurons are motor nerve cells that carry signals

from the CNS to the cells in the PNS. Each dendrite synapses with another cell body, axon, or dendrite and sends impulses along the efferent and afferent neuron pathways.

Many axons are covered by a **myelin sheath**—a white, lipid covering. Myelinated axons appear whitish and therefore are also called **white matter**. Nonmyelinated axons have a grayish cast and are called **gray matter**. Myelinated axons have gaps in the myelin called *nodes of Ranvier*. The nodes of Ranvier play a major role in impulse conduction (see Fig. 43-1). When the myelin is impaired, the impulses cannot travel from the brain to the rest of the body, such as in patients with multiple sclerosis.

The enlarged, distal end of each axon is called the *synaptic* or *terminal knob*. Within the synaptic knobs are the mechanisms for manufacturing, storing, and releasing a transmitter substance. Each neuron produces a specific **neurotransmitter** chemical (e.g., acetylcholine or serotonin) that can either enhance or inhibit the impulse but cannot do both. Other substances, although not specifically identified as neurotransmitters, are considered probable transmitters or neuromodulators.

Impulses are transmitted to their eventual destination through synapses, or spaces between neurons. There are two distinct types of synapses: *neuron to neuron* and *neuron to muscle* (or gland). Between the terminal knob and the next cell is a small space called the *synaptic cleft*. The knob, the cleft, and the portion of the cell to which the impulse is being transmitted make up the **synapse**.

Neuroglial Cells

Neuroglial cells, which vary in size and shape, provide protection, structure, and nutrition for the neurons. They are classified into four types: astroglial cells, ependymal cells, oligodendrocytes, and microglial cells. These cells are also part of the blood-brain barrier and help regulate cerebrospinal fluid (CSF).

Central Nervous System: Structure and Function

The central nervous system (CNS) is composed of the *brain*, which directs the regulation and function of the nervous system and all other systems of the body, and the *spinal cord*, which starts reflex activity and transmits impulses to and from the brain.

Brain

The **meninges** form the protective covering of the brain and the spinal cord. The outside layer is the *dura mater*. The **subdural space** is located between the dura mater and the middle layer, the *arachnoid*. The *pia mater* is the most inner layer. Situated between the arachnoid and pia mater is the **subarachnoid space**, where CSF circulates. A potential space, referred to as the *epidural space*, is located between the skull and the outer layer of the dura mater. This area also extends down the spinal cord and is used for the delivery of epidural analgesia and anesthesia.

The dura mater also lies between the cerebral hemispheres and the cerebellum and is called the *tentorium*. It helps decrease or prevent the transmission of force from one hemisphere to another and protect the lower brainstem when head trauma occurs. Clinical references may be made to a lesion (e.g., a tumor) as being **supratentorial** (above the tentorium) or **infratentorial** (below the tentorium).

FIG. 43-1 The structure of a typical neuron.

Major Parts of the Brain. The brain consists of three main areas—the brainstem, the cerebellum, and the forebrain. The *brainstem* connects the rest of the brain with the CNS. It is concerned primarily with life support and basic functions such as movement.

The *cerebellum* is concerned with coordination of movement and works together with the brainstem to focus on the functionality of the muscles. This structure is found below the occipital lobe and adjacent to the brainstem.

The *forebrain* lies above the brainstem and cerebellum and is the most advanced in evolution. This area of the brain is further divided into three areas—the diencephalon, the cerebrum, and the cerebral cortex.

The *diencephalon*, which lies below the cerebrum, includes the thalamus, hypothalamus, and epithalamus (Fig. 43-2). The *thalamus* is the major “relay station,” or “central switchboard,” for the CNS. The *hypothalamus* plays a major role in autonomic nervous system control (controlling temperature and other functions) and intellectual function (cognition). The epithalamus contains the roof of the third ventricle and the pineal gland.

The *cerebrum* is the largest part of the brain and controls intelligence, creativity, and memory. The “gray matter” of the cerebrum is the central cortex—the center that receives information from the thalamus and all the lower areas of the brain. The cerebrum consists of two halves, referred to as the *right hemisphere* and the *left hemisphere*, which are joined by the corpus callosum. The *left hemisphere* is the dominant hemisphere in most people (even in many left-handed people). Within the deeper structures of the cerebrum are the right and left lateral ventricles. At the base of the cerebrum near the ventricles is a group of neurons called the *basal ganglia*, which help regulate the need for *mobility*.

The *cerebral cortex* is part of the cerebrum and is involved with almost all of the higher functions of the brain. This part of the brain processes and communicates all information coming from the peripheral nervous system (PNS). It also translates the impulses into understandable feelings and thoughts. The cerebral cortex is so complex that it is further divided into four lobes—the frontal lobe, parietal lobe, temporal lobe, and occipital lobe.

The frontal lobe is found at the front of the head near the temples and forehead. It processes voluntary muscle

movements and higher functioning actions such as thought and speech. It also helps control mood, planning for the future, setting goals, and making judgments. The parietal lobe is found behind the frontal lobe. It processes spatial awareness and receives and processes information about temperature, taste, touch, and movement coming from the rest of the body. Reading and arithmetic are also processed in this lobe. The temporal lobes are located in the area of the brain parallel to the ears. They process hearing, memory, and language functions. The occipital lobe is located in the posterior of the brain and assists in the processing of visual information.

Located in the frontal lobe, the *motor cortex* controls voluntary movement. Corticospinal tracts, also called *pyramidal tracts*, begin in the motor cortex and travel through the brain before crossing in the medulla. This crossing explains how right motor cortex damage affects the movement in the left side of the body and vice versa, such as in many patients who have cerebral strokes. The cerebrum is divided into lobes by sulci (fissures). These lobes work together and are connected by nerve fibers. The name and main function of each lobe is listed in Table 43-1.

Two important speech areas of the cerebrum are Broca’s area and Wernicke’s area. *Broca’s area* (speech area), also located in the frontal lobe, is responsible for the formation of words, or speech. *Wernicke’s area* (language area) is located in the temporal lobe and allows processing of words into coherent thought and understanding of written or spoken words.

TABLE 43-1 CEREBRAL LOBE MAIN FUNCTIONS

Frontal Lobe

- The primary motor area (also known as the *motor “strip”* or *cortex*)
- Broca’s speech center on the dominant side
- Voluntary eye movement
- Access to current sensory data
- Access to past information or experience
- Affective response to a situation
- Regulates behavior based on judgment and foresight
- Judgment
- Ability to develop long-term goals
- Reasoning, concentration, abstraction

Parietal Lobe

- Understand sensation, texture, size, shape, and spatial relationships
- Three-dimensional (spatial) perception
- Important for singing, playing musical instruments, and processing nonverbal visual experiences
- Perception of body parts and body position awareness
- Taste impulses for interpretation

Temporal Lobe

- Auditory center for sound interpretation
- Complicated memory patterns
- Wernicke’s area for speech

Occipital Lobe

- Primary visual center

Limbic Lobe

- Emotional and visceral patterns connected with survival
- Learning and memory

FIG. 43-2 The structures of the brainstem and diencephalon.

The *hypophysis (pituitary gland)* has two lobes, each releasing specific hormones into the circulation under the regulation of the hypothalamus. The pituitary is often referred to as the “master gland” because of its control of numerous hormonal functions. However, the hypothalamus actually controls its functions.

The *cerebellum* receives immediate and continuous information about the condition of the muscles, joints, and tendons. Cerebellar function enables a person to:

- Keep an extremity from overshooting an intended target
- Move from one skilled movement to another in an orderly sequence
- Predict distance or gauge the speed with which one is approaching an object
- Control voluntary movement
- Maintain equilibrium

Unlike the motor cortex, cerebellar control of the body is **ipsilateral** (situated on the same side). The right side of the cerebellum controls the right side of the body, and the left cerebellum controls the left side of the body.

The brainstem includes the midbrain, pons, and medulla. The functions of these structures are presented in Table 43-2. Throughout the brainstem are special cells that constitute the **reticular activating system (RAS)**, which controls awareness and alertness. For example, this tissue awakens a person from sleep when presented with a stimulus such as loud noise or pain or when it is time to awaken. The reticular formation area has many connections with the cerebrum, the rest of the brainstem, and the cerebellum.

Circulation in the Brain. Circulation in the brain originates from the carotid and vertebral arteries (Fig. 43-3). The internal carotid arteries branch into the anterior cerebral

artery (ACA) and middle cerebral arteries (MCA), the largest ones. The two posterior vertebral arteries become the basilar artery, which then divides into two posterior cerebral arteries. The anterior, middle, and posterior cerebral arteries are joined together by small communicating arteries to form a ring at the base of the brain known as the **circle of Willis**.

The *middle* cerebral artery supplies the lateral surface of the cerebrum from about the mid-temporal lobe upward (i.e., the area for hearing and upper body motor and sensory neurons). The *anterior* cerebral artery supplies the midline, or medial, aspect of the same area (i.e., the lower body motor and sensory neurons). The *posterior* cerebral arteries supply the area from the mid-temporal region down and back

TABLE 43-2 BRAINSTEM FUNCTIONS

Medulla

- Cardiac-slowing center
- Respiratory center
- Cranial nerves IX (glossopharyngeal), X (vagus), XI (accessory), and XII (hypoglossal) emerge from the medulla, as do portions of cranial nerves VII (facial) and VIII (acoustic)

Pons

- Cardiac acceleration and vasoconstriction centers
- Pneumotaxic center helps control respiratory pattern and rate
- Four cranial nerves originate from the pons: V (trigeminal), VI (abducens), VII (facial), and VIII (vestibulocochlear)

Midbrain

- Contains the cerebral aqueduct or aqueduct of Sylvius
- Location of periaqueductal gray, which may abolish pain when stimulated
- Cranial nerve nuclei III (oculomotor) and IV (trochlear) located here

FIG. 43-3 Cerebral circulation and the circle of Willis at the base of the brain.

(occipital lobe), as well as much of the brainstem. When blood flow is interrupted in any of these arteries (e.g., by a clot), the area of the brain being supplied is affected and may not function as it should.

The *blood-brain barrier* (BBB) seems to exist because the endothelial cells of the cerebral capillaries are joined tightly together. This barrier keeps some substances in the bloodstream out of the cerebrospinal circulation and out of brain tissue. Substances that can pass through the BBB include oxygen, glucose, carbon dioxide, alcohol, anesthetics, and water. Large molecules such as albumin, any substance bound to albumin, and many antibiotics are prevented from crossing the barrier.

Cerebrospinal fluid (CSF) also circulates, surrounds, and cushions the brain and spinal cord. While moving through the subarachnoid space, the fluid is continuously produced by the choroid plexus, reabsorbed by the arachnoid villi, and then channeled into the superior sagittal sinus. Expanded areas of subarachnoid space, where there are large amounts of CSF, are called *cisterns*. The largest one is the lumbar cistern, the site of lumbar puncture, from the level of the second lumbar vertebra to the second sacral vertebra (L2-S2).

Spinal Cord

The spinal cord controls body movement (*mobility*); regulates organ function; processes sensory information from the extremities, trunk, and many internal organs (*sensation*); and transmits information to and from the brain. It contains H-shaped **gray matter** (neuron cell bodies) that is surrounded by **white matter** (myelinated axons). The white matter is divided into posterior, lateral, and anterior columns. Groups of cells in the white matter (ascending and descending tracts) have been fairly well identified (Fig. 43-4).

Ascending Tracts. *Ascending tracts* originate in the spinal cord and end in the brain. Three groups of ascending tracts are important for understanding the patient with neurologic problems: spinothalamic tracts, spinocerebellar tracts, and fasciculi gracilis and cuneatus (posterior white columns).

As the name indicates, *spinothalamic* tracts begin in the spinal cord with most ending in the thalamus. These tracts carry sensations of pain, temperature, light touch, and

pressure. The axon fibers from the cells cross to the opposite side and then continue up to the thalamus. Some branches end in the medulla and pons.

Spinocerebellar tracts begin in the spinal cord and end in the cerebellum. The *posterior* spinocerebellar tract transmits impulses of **proprioception** (awareness of position and movements of body parts) or movement, mostly from the lower extremities. The impulses enter the posterior gray horn and synapse with tract cells in lamina VII. Spinocerebellar axons then form the tract on the *same*, or ipsilateral, side. This tract begins at the second lumbar level and ascends to the medulla and then to the cerebellum.

The *anterior* spinocerebellar tract begins lower in the lumbar spine than does the posterior tract. These fibers cross immediately and ascend as an opposite-side tract, transmitting proprioceptive impulses from the lower extremities. The fibers cross again in the midbrain on their way to the cerebellum. Because these fibers have crossed the midline twice, the sensations end on the side on which they started.

The *posterior white columns* transmit this information to the thalamus:

- The sensation of proprioception from muscles, joints, and tendons
- Vibratory sense
- Light touch from the skin
- Localization

Most of the fibers ascend on the *same* side as their origin to the medulla, where they cross and then synapse in the thalamus, with termination in the parietal lobe. This tract allows a person to feel an exact point of pressure on the skin. Recognition of pressure includes the shape of an object (with eyes closed), movement across the skin (a number being written), and awareness of two points of touch close together (two-point discrimination).

Descending Tracts. *Descending tracts* begin in the brain and end in the spinal cord. The major descending tract of importance for understanding neurologic problems is the lateral *corticospinal*, or *pyramidal*, tract. The corticospinal tract originates in the motor cortex of the frontal lobe and portions of the parietal lobe. The lateral tract fibers cross to the opposite side at the level of the medulla. After crossing, the fibers descend and synapse with interneurons of the gray

FIG. 43-4 A cross section of the spinal cord showing the common tracts.

matter in the spinal cord. These few fibers connect directly with lower motor neurons (LMNs). The cervical spine has a high concentration of fibers synapsing with interneurons, which possibly reflects the complexity of hand and finger movements.

The motor neurons of the other descending tracts and the basal ganglia used to be referred to as an *extrapyramidal system*. It was thought that pyramidal neurons caused voluntary muscle activity and that extrapyramidal neurons caused automatic or involuntary muscle action. However, all of the descending tracts and the basal ganglia are necessary for *mobility*. The term *extrapyramidal* is still often used clinically, meaning *abnormal spontaneous movement*.

Peripheral Nervous System: Structure and Function

The peripheral nervous system (PNS) is composed of the spinal nerves, cranial nerves, and autonomic nervous system.

There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal) exiting from the spinal cord. Each of the nerves has a posterior and an anterior branch. The posterior branch carries sensory information (sensation) to the cord (*afferent pathway*). The anterior branch transmits motor impulses (mobility) to the muscles of the body (*efferent pathway*).

Each spinal nerve is responsible for the muscle innervation and sensory reception of a given area of the body. The cervical and thoracic spinal nerves are relatively close to their areas of responsibility, whereas the lumbar and sacral spinal nerves are some distance from theirs. Because the spinal cord ends between L1 and L2, the axons of the lumbar and sacral cord extend downward before exiting at the appropriate intervertebral foramen. The area controlled by each spinal nerve is roughly reflected in the dermatomes. **Dermatomes** represent sensory input from spinal nerves to specific areas of the skin (Fig. 43-5). For example, the patient with an injury to cervical spinal nerves C6 and C7 has sensory changes in the thumb,

FIG. 43-5 Dermatomes (cutaneous innervation of spinal nerves).

index finger, middle finger, middle of the palm, and back of the hand.

Sensory receptors throughout the body monitor and transmit impulses of pain, temperature, touch, vibration, pressure, visceral sensation, and proprioception. Sensory receptors also monitor and transmit the sensations of the special senses—vision, taste, smell, and hearing.

The cell bodies of the anterior spinal nerves are located in the anterior gray matter (anterior horn) of each level in the spinal cord. The anterior motor neurons are also referred to as *lower motor neurons*. As each nerve axon leaves the spinal cord, it joins other spinal nerves to form **plexuses** (clusters of nerves). Plexuses continue as trunks, divisions, and cords and finally branch into individual peripheral nerves.

The **reflex arc** is a closed circuit of spinal and peripheral nerves and therefore requires no control by the brain (Fig. 43-6).

Reflexes consist of sensory input from:

- Skeletal muscles, tendons, skin, organs, and special senses
- Small cells in the spinal cord lying between the posterior and anterior gray matter (interneurons)
- Anterior motor neurons, along with the muscles they innervate

There are 12 *cranial nerves*. Their name, number, origin, type, and function are summarized in Table 43-3. Cranial nerve function is an important part of the nursing assessment of the patient with a neurologic problem. For example, cranial nerves II, III, IV, and VI are important for assessment of the patient with a stroke.

Autonomic Nervous System: Structure and Function

The **autonomic nervous system (ANS)** is composed of two parts: the sympathetic nervous system (SNS), or the “fight or flight system”; and the parasympathetic nervous system. ANS functions are not usually under conscious control but may be

altered in some people by using biofeedback and other methods.

The SNS cells originate in the gray matter of the spinal cord from T1 through L2 or L3. This part of the ANS is considered *thoracolumbar* because of its anatomic location. The SNS stimulates the functions of the body needed for “fight or flight” (e.g., heart and respiratory rate). It also inhibits those functions not needed in this situation.

The parasympathetic cells originate in the gray matter of the sacral area of the spinal cord (from S2 through S4) plus portions of cranial nerves III, VII, IX, and X (*craniosacral*). The parasympathetic nervous system can slow body functions when needed.

Parasympathetic fibers to the organs have some sensory ability in addition to motor function. Sensations of irritation, stretching of an organ, or a decrease in tissue oxygen are transmitted to the thalamus through pathways not yet fully understood. Because pain from internal organs is often felt below the body wall innervated by the spinal nerve, it is presumed that there are connections between the viscera and body structure that relay pain sensations.

Neurologic Changes Associated with Aging

Neurologic changes associated with aging often affect mobility and sensation. *Motor changes* in late adulthood can cause slower movement and response time and decreased sensation (Chart 43-1). Any problems that affect the nerves, bones, muscles, or joints also affect motor and therefore ADL ability.

Sensory changes in older adults can also affect their daily activities. Pupils decrease in size, which restricts the amount of light entering the eye, and adapt more slowly. Older adults need increased lighting to see. Touch sensation decreases, which may lead to falls because the older person may not feel small objects or a step underfoot. Vibration sense may be lost in the ankles and feet. These changes can contribute to falls. (See the discussion on fall prevention in Chapter 3.) Hearing also decreases, especially for high-pitched sounds.

FIG. 43-6 An example of reflex activity. Stimulation of skin results in involuntary muscle contraction (reflex arc).

TABLE 43-3 ORIGINS, TYPES, AND FUNCTIONS OF THE CRANIAL NERVES

CRANIAL NERVE	ORIGIN	TYPE	FUNCTION
I: Olfactory	Olfactory bulb	Sensory	Smell
II: Optic	Midbrain	Sensory	Central and peripheral vision
III: Oculomotor	Midbrain	Motor to eye muscles	Eye movement via medial and lateral rectus and inferior oblique and superior rectus muscles; lid elevation via the levator muscle
		Parasympathetic-motor	Pupil constriction; ciliary muscles
IV: Trochlear	Lower midbrain	Motor	Eye movement via superior oblique muscles
V: Trigeminal	Pons	Sensory	Sensation from skin of face and scalp and mucous membranes of mouth and nose
		Motor	Muscles of mastication (chewing)
VI: Abducens	Inferior pons	Motor	Eye movement via lateral rectus muscles
VII: Facial	Inferior pons	Sensory	Pain and temperature from ear area; deep sensations from the face; taste from anterior two thirds of the tongue
		Motor	Muscles of the face and scalp
		Parasympathetic-motor	Lacrimal, submandibular, and sublingual salivary glands
VIII: Vestibulocochlear	Pons-medulla junction	Sensory	Hearing Equilibrium
IX: Glossopharyngeal	Medulla	Sensory	Pain and temperature from ear; taste and sensations from posterior one third of tongue and pharynx
		Motor	Skeletal muscles of the throat
		Parasympathetic-motor	Parotid glands
X: Vagus	Medulla	Sensory	Pain and temperature from ear; sensations from pharynx, larynx, thoracic and abdominal viscera
		Motor	Muscles of the soft palate, larynx, and pharynx
		Parasympathetic-motor	Thoracic and abdominal viscera; cells of secretory glands; cardiac and smooth muscle innervation to the level of the splenic flexure
XI: Accessory	Medulla (anterior gray horn of the cervical spine)	Motor	Skeletal muscles of the pharynx and larynx and sternocleidomastoid and trapezius muscles
XII: Hypoglossal	Medulla	Motor	Skeletal muscles of the tongue

CHART 43-1 NURSING FOCUS ON THE OLDER ADULT***Changes in the Nervous System Related to Aging***

PHYSIOLOGIC CHANGES	NURSING IMPLICATIONS	RATIONALES
Slower processing time	Provide sufficient time for the affected older adult to respond to questions and/or direction.	Allowing adequate time for processing helps to differentiate normal findings from neurologic deterioration.
Recent memory loss	Reinforce teaching by repetition and written teaching aids.	Greatest loss of brain weight is in the white matter of the frontal lobe. Intellect is not impaired, but the learning process is slowed. Repetition helps the patient learn new information and recall it when needed.
Decreased touch sensation	Remind the patient to look where his or her feet are placed when walking. Instruct the patient to wear shoes that provide good support when walking. If the patient is unable, change his or her position frequently (every hour) while he or she is in bed or the chair.	Decreased sensation may cause the patient to fall.
Change in perception of pain	Ask the patient to describe the nature and specific characteristics of pain. Monitor additional assessment variables to detect possible health problems.	Accurate and complete nursing assessment ensures that the interventions will be appropriate for the older adult (see Chapter 3).
Change in sleep patterns	Ascertain sleep patterns and preferences. Ask if sleep pattern interferes with ADLs. Adjust the patient's daily schedule to his or her sleep pattern and preference as much as possible (e.g., evening versus morning bath).	Most older adults require less sleep than do younger adults. However, frequent rest periods are needed.
Altered balance and/or decreased coordination	Instruct the patient to move slowly when changing positions. If needed, advise the patient to hold on to handrails when ambulating. Assess the need for an ambulatory aid, such as a cane.	The patient may fall if moving too quickly. Assistive and adaptive aids provide support and prevent falls.
Increased risk for infection	Monitor carefully for infection.	Older adults often have structural deterioration of microglia, the cells responsible for cell-mediated immune response in the central nervous system (CNS).

Cognitive functions of perceiving, registering, storing, and using information often change as a normal part of aging. Therefore it is important to differentiate between these expected findings and those of dementia, depression, and delirium (3Ds). Failure to correctly diagnosis pathologic cognitive problems may lead to a poor patient outcome.

Intellect does not decline as a result of aging. However, a person with certain health problems may have a decrease in cognitive level. *Cognitive decline is frequently caused by drug interactions or toxicity or by an inadequate oxygen supply to the brain.* Some older adults may need more time than a younger person to process questions, learn and process new information, solve problems, or complete analogies (Vance, 2009).

Subtle memory changes are typical for many older people. Long-term memory seems better than recall (recent) or immediate (registration) memory. Older adults may need more time to retrieve information. These changes may be partly due to the loss of cerebral neurons, which is associated with the aging process.

Circadian rhythm disorders may lead to wakefulness until later at night, with extended sleeping in the morning (a pattern opposite that of most health care facility routines). Many older adults require less sleep than do their younger counterparts.

Mental status may also decline as a result of infection. *Often this change in mental status is a key early sign of an infectious process in the older patient, especially urinary tract infection.*

ASSESSMENT METHODS

Patient History

During your introduction, note the patient's appearance and assess his or her speech, affect, and motor function. If he or she seems to have cognitive deficits or has trouble speaking or hearing, ask a family member or significant other to stay during the interview to help obtain an accurate history. Be sure that glasses, contact lenses, and hearing aids are available if the patient wears any of these aids.

Ask the patient about his or her medical history to determine its association with the current health problem. Inquire about the ability to perform ADLs. Knowing the level of daily activity helps establish a baseline for later comparison as the patient improves or worsens. Ask whether the patient is right-handed or left-handed. This information is important for several reasons:

- The patient may be somewhat stronger on the dominant side, which is expected.
- The effects of cerebral injury or disease are more pronounced if the dominant hemisphere is involved.

Family History and Genetic Risk

Ask about family medical history such as stroke or myocardial infarction (MI) (heart attack). Some diseases occur more often in certain groups of people and may be caused by a genetic influence or other reason. For example, it has been long established that Huntington disease is inherited. A number of other neurologic diseases have a genetic basis, such as neuromuscular disorders, migraine headaches, and epilepsy. These genetic risks are described with specific neurologic diseases found later in this unit.

Current Health Problems

Obtain information from the patient about current health problems as outlined in [Charts 43-2 and 43-3](#).

Physical Assessment

Perform a focused assessment based on the patient's current health problems. Compare each assessment with the patient's baseline, as well as between right and left sides and between upper and lower extremities. Most of the assessment can be performed with the patient sitting or lying down. *Two types of neurologic assessments may be performed—a complete assessment and a “rapid” assessment.* The method chosen depends on the information needed, the time available with the patient, and your clinical skill level. Advanced practice nurses (APNs) and other health care providers usually perform the complete assessment, although parts of it can be done by any nurse. It is important that you understand each component of the assessment and what the results might indicate. The complete assessment is described first.

Assessment of Mental Status

While collecting the history data, make observations about the patient's mental status, speech, and behavior as noted in [Chart 43-4](#). An organized head-to-toe physical assessment begins with the mental status.

CHART 43-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Establishing a Nursing Database: History

Demographic Data

- Age
- Gender

Past Medical History

- Patient's medical history
- Family's medical history
- Previous injuries or congenital problems
- Chronic diseases:
 - Hypertension
 - Diabetes mellitus
 - Lung disease
- Previous neurologic problems:
 - Headaches
 - Seizures
 - Head or spine trauma
 - Eye problems
 - Stroke

Current History

- Current symptoms:
 - Blurred vision
 - Headache
 - Speech or swallowing difficulty
 - Numbness, tingling
 - Weakness, clumsiness
 - Bowel or bladder difficulties
 - Nausea or vomiting
 - Personality changes
 - Seizures
 - Disorientation or other change in mental status

Allergies:

- Food
- Medications
- Environment

Pain tolerance:

- Medications taken for pain
- Behaviors to reduce pain
- Medications:
 - Prescribed
 - Illicit
 - Over-the-counter
- ADLs

Social History

- Usual recreational activities
- Level of physical activity each day
- Hobbies
- Alcohol consumption and use of recreational drugs
- Smoking, use of any tobacco products
- Sleep habits:
 - Changes in pattern, duration, or intensity
- Work history:
 - Exposure to toxic agents
- Ethnic and cultural background
- Handedness (right or left)
- Educational background

Level of Consciousness and Orientation. Determine level of consciousness (LOC) by observing the patient's responsiveness and mental status.

! NURSING SAFETY PRIORITY

Action Alert

Be aware that a change in LOC is the **first** indication that central neurologic function has declined! The patient who is described as **alert** is awake and responsive. A patient may be alert but not oriented to person, place, or time. Patients who are less than alert are labeled **lethargic**, **stuporous**, or **comatose**. A **lethargic** patient is drowsy or sleepy but is easily awakened. One who is arousable only with vigorous or painful stimulation is **stuporous**. The **comatose** patient is unconscious and cannot be aroused.

CHART 43-3 NEUROLOGIC ASSESSMENT

Using Gordon's Functional Health Patterns

Health Perception–Health Management Pattern

- How would you describe your general health?
- Has your health changed significantly over the past few weeks or months?
- Have you had to miss any work because of changes in your health?

Cognitive-Perceptual Pattern

- Have you noticed any changes in your vision? Hearing? Memory?
- Do you feel you are having any difficulty in making decisions? In learning?
- Are you experiencing any discomfort? Pain? Weakness?

Activity-Exercise Pattern

- Do you have enough energy for your activities?
 - What is your perceived ability for (code for level according to key below):
- | | |
|-------------------|---|
| Feeding? | Level 0: Full self-care |
| Bathing? | Level I: Requires use of equipment or device |
| Toileting? | |
| Bed mobility? | Level II: Requires assistance or supervision of another person |
| Dressing? | |
| Grooming? | Level III: Requires assistance or supervision of another person |
| General mobility? | |
| Cooking? | and equipment or device |
| Home maintenance? | Level IV: Is dependent and does not participate |
| Shopping? | |

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

CHART 43-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessment of Mental Status

- Are the patient's answers appropriate?
- Are the patient's behavior and facial expression appropriate?
- Is the speech pattern of normal tone, rate, rhythm, and volume?
- Are the answers complete?
- Is the patient's appearance neat or untidy? Appropriate for age and weather conditions?
- Is the patient cooperative, euphoric, hostile, anxious, withdrawn, or guarded?
- Is the patient experiencing hallucinations or delusions?
- Are the patient's posture and hygiene appropriate for the situation?
- Is the patient drowsy?

To best identify the patient's level of cognitive function or state of consciousness, describe behavior as response to stimulation. If alert, ask him or her questions to determine orientation. Varying the sequence of questioning on repeated assessments prevents the patient from memorizing the answers. Responses that indicate orientation include:

- The patient's ability to relate the onset of symptoms
- The name of his or her physician/nurse practitioner/nurse
- The year and month
- His or her address
- The name of the referring physician or health care agency

Advanced age, time of day, drug therapy, and the need for sleep, glucose, or oxygen may affect these responses.

Memory and Attention. Memory is one of the most important parts of the neurologic assessment. If the patient cannot remember, most of the verbal assessment tests are not useful. *Loss of memory, especially recent memory, tends to be an early sign of neurologic problems.* Three types of memory can be tested: long-term (remote) memory, recall (recent) memory, and immediate memory.

Remote, or long-term, **memory** can be tested by asking patients about their birth date, schools attended, the city of birth, or anything from the past that can be verified. Nurses often ask the maiden name of the patient's mother, which is sometimes listed on the admission form and can be checked.

Recall (recent) **memory** can be tested during the history and checked on the medical record:

- The accuracy of the medical history
- Dates of clinic or physician appointments
- The time of admission
- Health care providers seen within the past few days
- Mode of transportation to the hospital or clinic

Immediate (new) **memory** is tested by giving the patient two or three unrelated words, such as "apple," "street," and "chair," and asking him or her to repeat the words to make sure they were heard. After about 5 minutes, while continuing with the examination, ask the patient to repeat the words. An alternative to this method is to give a three-step command and observe whether it is carried out correctly. For example, "Pick up the paper, fold it in half, and draw a square on it."

To assess **attention**, ask the patient to repeat a series of three numbers, such as 4, 7, and 3. The series is increased by one number with each successful repetition until seven or eight digits are achieved. If the patient has difficulty at any level (cannot repeat the series), repeat the numbers. If the patient cannot repeat, stop the procedure. Next, ask the patient to repeat the numbers backward, starting again with three digits and increasing by one each time. Normally, a person should be able to repeat five to eight digits forward and four to six backward. Education, occupation, interest, culture, anxiety, and depression affect mental status, and what is considered "normal" may not be so for a particular patient.

The serial-seven test to determine attention may also be used. The patient is asked to count backward from 100 by 7 (the examiner stops when the patient reaches 65 successfully). Depending on education and other factors, it may be better to ask the person to subtract by three or to add forward by five. Clinical judgment and assessment skills are used when deciding which of these tests to use.

Language and Higher Levels of Cognition. If desired, most *language* and *copying* skills can be assessed during the initial interview. The patient demonstrates understanding by following directions on admission (e.g., getting undressed). If he or she hesitates, indicating word searching, point to objects and ask the patient to name them, such as the door or bed.

The advanced practice nurse (APN) or speech-language pathologist (SLP) tests reading comprehension by writing a simple command and giving it to the patient (e.g., “close your eyes”). Writing can be tested by asking the patient to write a sentence. The clinician must remember that some patients cannot read or write or may speak a language different from that of the clinician. In this case, modify the examination accordingly. Copying ability is usually tested by having the patient copy something that has been drawn, such as a cross, circle, diamond, or square.

Higher intellectual functions are assessed by asking about favorite hobbies, current events, the names of the last few presidents. Abstract reasoning can be evaluated by asking the meaning of proverbs (e.g., “A stitch in time saves nine” or “A rolling stone gathers no moss”). *People from countries other than the United States or young adults may be unfamiliar with some of these abstract statements.* Consult a professional language interpreter to assist with language and speech assessment.

Begin to assess the patient’s judgment during the interview. Did he or she make rational decisions in dealing with his or her symptoms? Ask questions such as “What would you do if stopped for speeding?” and “What would you do if there was a fire in the wastepaper basket?” *Remember that testing of cognition (general knowledge, abstraction, and judgment) is influenced by culture.* For example, in some cultures (e.g., Nigerian, Chinese), men make all decisions or answer these questions for their wives or other female family members.

Assessment of Cranial Nerves

Cranial nerves are typically tested to establish a baseline from which to compare progress or deterioration. However, they are not routinely tested unless the patient has a suspected problem affecting one or more of the cranial nerves (see Table 43-3). The testing of cranial nerve III is usually a part of the rapid neurologic assessment described on p. 917. Adding the specific cranial nerves to be tested on the flow sheet of a patient with a problem affecting the cranial nerves helps ensure continued comparison and assessment.

Assessment of Sensory Function

The assessment of sensory function is done for patients with problems affecting the spinal cord or spinal nerves, such as trauma, intervertebral disk disease, Guillain Barré syndrome (GBS), tumor, infection, stenosis, or transverse myelitis. The sensory assessment includes pain, superficial and deep sensation, light touch, and proprioception. *Pain and light touch are the most commonly assessed.*

The acuity level of the patient determines how often the sensory assessment is done. For example, patients with acute spinal cord trauma or ascending GBS are assessed every hour until stable and then every 4 hours. As the condition improves, sensory assessment may be needed only once each shift. Findings are documented according to agency protocol. A special spinal cord assessment flow sheet may be used to document

sensory and/or motor findings for the patient with a spinal cord injury.

Pain and temperature sensations are transmitted by the same nerve endings. Therefore if one sensation is tested and found to be intact, it can safely be assumed that the other is intact. Testing temperature sensation can usually be accomplished using a cold reflex hammer and the warm touch of the hand for patients with known or suspected spinal problems.

Assess for *pain sensation* with any sharp or dull object, such as a cotton-tipped applicator or paper clip. Demonstrate what will be done while the patient’s eyes are open. Then, ask him or her to keep eyes closed and to indicate whether the touch is sharp or dull. The sharp and dull ends should be changed at random so he or she does not anticipate the next type of sensation. Not all areas need to be tested unless a spinal cord injury has occurred. If testing begins on the hands and feet, there is no need to test the other parts of the extremities because the tracts transmitting pain and temperature sensations are intact. Compare reactions on each side. A sensation reported as dull when the stimulus was actually sharp requires further testing. A patient with sensory loss as a result of diabetes mellitus or peripheral vascular disease may or may not be aware of the loss until tested. Some patients with chronic illness may report that they have had sensory losses for a long time.

Light touch discrimination is likely to be normal if pain and temperature sensations are intact. Touch discrimination and two-point discrimination may be performed as part of a complete neurologic examination by the physician or APN.

For testing **touch discrimination**, the patient closes his or her eyes. The practitioner touches the patient with a finger and asks that he or she point to the area touched. This procedure is repeated on each extremity at random rather than at sequential points. Next, the practitioner touches the patient on each side of the body on corresponding sites at the same time. The patient should be able to point to both sites.

The clinician then touches the patient in two places on the same extremity with two objects, such as cotton-tipped applicators. A person can normally identify two points fairly close together depending on the location of the stimuli. When an area is heavily innervated, the *two-point discrimination will feel closer*.

Abnormal sensory findings may have a peripheral nervous system (PNS) or a central nervous system (CNS) cause. The neuropathies of diabetes, malnutrition, and vascular problems have a PNS cause and generally involve the entire extremity or both extremities. Damage to a specific spinal nerve may not result in significant sensory loss because the spinal nerves overlap. Injury to several nearby spinal nerves is manifested as decreased or absent sensation in the dermatomes of those nerves.

CNS problems can occur within the spinal cord, the brainstem, the cerebellum, and the cerebral cortex. Sensory deficits from spinal cord damage vary with the location of the damage. Involvement of only the posterior column leads to lost **proprioception** (position sense) below the level of the damage on the same side or on both sides (if both the right and left posterior columns are involved). A lesion involving only the right spinothalamic tract results in a loss of pain and temperature sensation below the lesion on the *left* side. Problems in the brainstem, thalamus, and cortex generally result

FIG. 43-7 Testing for strength against resistance.

in loss of sensation on the **contralateral** (opposite) side of the body. Cerebellar lesions affect sensation on the *same* side of the body.

Assessment of Motor Function

Throughout the physical assessment, observe the patient for involuntary tremors or movements. Describe these movements as accurately as possible, such as “pill-rolling with the thumbs and fingers at rest” or “intention tremors of both hands” (tremors that occur when the patient tries to do something). These abnormalities can indicate certain diseases, such as multiple sclerosis, or the effects of selected psychotropic drugs.

Measure the patient’s hand *strength* by asking him or her to grasp and squeeze two fingers of each of your hands. Then compare the grasps for equality of strength. As another means of evaluating strength, try to withdraw the fingers from the patient’s grasp and compare the ease or difficulty. He or she should release the grasps on command—another assessment of consciousness and the ability to follow commands.

To test the patient’s strength against resistance, ask him or her to resist your bending or straightening of the arm, hand, leg, or foot being tested (Fig. 43-7). A five-point rating scale is commonly used (see Chapter 52, Table 52-2). Test results are sometimes recorded as 5/5, 3/5, and so forth, indicating the criteria that were used and the status of the patient at that testing. Always evaluate and compare strength on each side. Later testing results are compared with previous results to indicate any change.

Cerebral motor or *brainstem* integrity may also be assessed. Ask the patient to close his or her eyes and hold the arms perpendicular to the body with the palms up for 15 to 30 seconds. If there is a cerebral or brainstem reason for muscle weakness, the arm on the weak side will start to fall, or “drift,” with the palm pronating (turning inward). This is called a **pronator drift**. The same can be done for the lower extremities, with the patient lying on his or her stomach with the legs bent upward at the knees. However, it is easier for most patients to sit on the side of the bed and extend the legs outward.

Assessment of Cerebellar Function

Most of the assessment of cerebellar function can be performed with the patient sitting on the side of the bed or examining table. Fine *coordination* of muscle activity is tested.

If cerebellar problems are suspected or diagnosed, ask the patient to perform these tasks with his or her eyes closed:

- Run the heel of one foot down the shin of the other leg, and repeat with the other leg (the patient should be able to do this smoothly and keep the heel on the shin).
- Place the hands palm-up and then palm-down on each thigh, repeating as fast as possible (this can normally be done rapidly).
- With arms out at the side, touch the finger to the nose two or three times, with eyes open and then with eyes closed (this can be done with alternating arms or with each arm individually).

For the last part of the cerebellar assessment, the *ambulatory* patient stands for testing of *gait and equilibrium*. Gait and equilibrium are usually tested at the end or beginning of the entire neurologic assessment. Ask the patient to walk across the room, turn, and return. Observe for uneven steps, difficulty walking, and so forth. To evaluate balance, ask him or her to stand on one foot and then on the other. Tiptoe walking and heel-to-toe walking can also demonstrate gait problems. For patients with sciatic nerve involvement, pain may worsen when they walk on their toes or heels.

To test equilibrium, ask the patient to stand with arms at the sides, feet and knees close together, and eyes open. Check for swaying, and then ask him or her to close his or her eyes and maintain position. The examiner should be close enough to prevent falling if the patient cannot stay erect. If he or she sways with the eyes closed but not when the eyes are open (the **Romberg sign**), the problem is probably **proprioceptive** (awareness of body position). If the patient sways with the eyes both open and closed, the neurologic disturbance is probably *cerebellar* in origin.

If the patient cannot perform any of these activities smoothly, the problem is manifested on the same side as the cerebellar lesion. If both lobes of the cerebellum are involved, the incoordination affects both sides of the body (bilateral).

Assessment of Reflex Activity

The health care provider, including the APN, may assess deep tendon reflexes (DTRs) and superficial (cutaneous) reflexes. The **deep tendon reflexes** of the biceps, triceps, brachioradialis, and quadriceps muscles and of the Achilles tendon can be tested as part of the routine neurologic assessment. Striking the tendon with the reflex hammer should cause contraction of the muscle (Fig. 43-8). The appropriate muscle contraction indicates an intact reflex arc. The tendon is tapped quickly but not with too much force. If the patient is tensing the muscle, the reflexes will not respond. Having the patient interlock his or her hands and pull outward will help decrease muscle tensing so the reflex can be tested.

The **cutaneous (superficial) reflexes** usually tested are the plantar reflexes and sometimes the abdominal reflexes. The plantar reflex is tested with a pointed (but not sharp) object, such as the handle end of the reflex hammer or the rounded end of bandage scissors. The normal response is plantar flexion of all toes. Dorsiflexion of the great toe and fanning of the other toes (**Babinski’s sign**) is abnormal in anyone older than 2 years and represents the presence of central nervous system (CNS) disease. The term “positive Babinski’s sign” (abnormal response) and “negative Babinski’s sign” (normal response) are clinically used terms but are not correct. **Babinski’s sign** is a pathologic, or

FIG. 43-8 Procedures for testing deep tendon reflexes.

abnormal, reflex. Health care providers may also use the terms “upgoing” or “downgoing” to refer to the toes of the stimulated foot. “Upgoing” toes is an abnormal response that indicates the presence of pathology in the CNS. Babinski’s sign can occur with drug and alcohol intoxication, after a seizure, or in patients with multiple sclerosis or liver disease.

To test the abdominal reflex, stroke the patient’s abdomen in all four quadrants diagonally toward the umbilicus. The umbilicus should deviate toward the stimulus, but obesity may mask the reflex. The abdominal reflex can be absent in both upper and lower motor neuron disease.

Hyperactive reflexes indicate possible upper motor neuron disease, tetanus, or hypocalcemia. *Hypoactive* reflexes may result from lower motor neuron disease (damage to the spinal cord), disease of the neuromuscular junction, muscle disease, or health problems such as diabetes mellitus, hypothyroidism, or hypokalemia.

Asymmetry of reflexes is an important finding because it probably indicates a disease process. The results of reflex testing are recorded by the use of a stick figure and a scale of 0 to 4 (Fig. 43-9). A score of 2 is considered normal, although scores of 1 (hypoactive) or 3 (stronger than normal) may be normal for a particular patient. **Clonus** (also called *myoclonus*) is the sudden, brief, jerking contraction of a muscle or muscle group often seen in seizures.

Rapid Neurologic Assessment

A rapid neurologic assessment, or “neuro check,” is completed when the patient is admitted to a health care facility on an emergent basis. It is also part of ongoing patient assessment and performed in the event of a sudden change in neurologic status. The typical flow sheet contains data related to level of consciousness, orientation, movement of arms and

FIG. 43-9 A stick figure and scale for recording reflex activity.

legs, and pupil size and reaction to light. *Be sure to document all aspects of the rapid neurologic assessment.*

As part of the flow sheet or on a separate form, the **Glasgow Coma Scale (GCS)** (Fig. 43-10) is used in most health care agencies to help describe the patient’s level of consciousness (LOC). This tool has been shown to be very reliable for most patients. Some agencies use the GCS along with other assessment findings for a more comprehensive picture of the patient’s condition.

GLASGOW COMA SCALE*	
Eye Opening	
Spontaneous	4
To sound	3
To pain	2
Never	1
Motor Response	
Obeys commands	6
Localizes pain	5
Normal flexion (withdrawal)	4
Abnormal flexion	3
Extension	2
None	1
Verbal Response	
Oriented	5
Confused conversation	4
Inappropriate words	3
Incomprehensible sounds	2
None	1

* The highest possible score is 15

FIG. 43-10 The Glasgow Coma Scale.

The GCS establishes baseline data in each of these areas: eye opening, motor response, and verbal response. The patient is assessed and assigned a numeric score for each of these areas. A score of 15 represents normal neurologic functioning. A score of 7 represents a comatose state. Thus the lower the score, the lower the patient's LOC. For patients who are intubated and cannot talk, record their score with a "t" after the number. The best possible score for this patient would be 11t.

Use the most appropriate stimulus for getting a response. If the patient is not awake and responding to commands, it may be necessary to use painful stimuli to obtain the best response. The patient's response to central pain (brain response) is assessed first. On the basis of this response, peripheral pain may then be assessed. Failure to apply painful stimuli appropriately may lead to an incorrect conclusion about the patient's neurologic status.

To apply vigorous stimuli, start with the least noxious irritation or pressure and proceed to more painful stimulation if the patient does not respond. Begin each phase of the assessment by speaking in a normal voice. If no response is obtained, use a loud voice. If the patient does not respond, gently shake him or her. The shaking should be similar to that used in attempting to wake up a child. If that is unsuccessful, apply painful stimuli using one of these methods:

- Supraorbital (above eyes) pressure
- Trapezius muscle squeeze
- Mandibular (jaw) pressure
- Sternal (breastbone) rub

FIG. 43-11 Posturing. **A**, Decorticate posturing. **B**, Decerebrate posturing.

First, apply supraorbital pressure by placing a thumb under the orbital rim in the middle of the eyebrow and pushing upward. *Do not use this technique if the patient has orbital or facial fractures.*

A second technique to elicit pain is to pinch or squeeze the trapezius muscle located at the angle of the shoulder and neck muscle. If the patient remains unresponsive, apply pressure to the jaw using your index and middle fingers. If the patient does not respond, make a fist and rub the knuckles of your hand against the sternum in a twisting motion. The tissue in this area is tender, and bruising is not unusual. Therefore do not use this technique for older adults or for patients who bruise easily (e.g., those on anticoagulant therapy).

The patient may respond to painful stimuli in several ways. Although the initial response to pain may be abnormal flexion or extension, continued application of pain for no more than 20 to 30 seconds may demonstrate that he or she can localize or withdraw. If the patient does not respond after 20 to 30 seconds, stop applying the painful stimulus.

In addition to using the GCS, observe the patient for other signs of altered mental status. These changes include reports of headache; restlessness, irritability, or being unusually quiet; slurred speech; and a change in the level of orientation.

Decortication is abnormal posturing seen in the patient with lesions that interrupt the corticospinal pathways (Fig. 43-11, A). The patient's arms, wrists, and fingers are flexed with internal rotation and plantar flexion of the legs. **Decerebration** is abnormal posturing and rigidity characterized by extension of the arms and legs, pronation of the arms, plantar flexion, and opisthotonos (body spasm in which body is

! NURSING SAFETY PRIORITY

Critical Rescue

Decerebrate or decorticate posturing, as well as pinpoint or dilated and nonreactive pupils, is a late mental deterioration sign. Notify the health care provider immediately of any change in mental status to possibly prevent further decline!

bowed forward) (Fig. 43-11, *B*). Decerebration is usually associated with dysfunction in the brainstem area.

Assess the patient's pupils as part of ongoing "neuro checks." Pupil constriction is a function of cranial nerve III, the oculomotor nerve. Pupils should be **equal** in size, **round** and **regular** in shape, and react to **light** and **accommodation** (**PERRLA**). Estimate the size of both pupils using a millimeter ruler. Patients who have had eye surgery for cataracts or glaucoma often have irregularly shaped pupils. Those using eyedrops for either cataracts or glaucoma may have unequal pupils if only one eye is being treated, and the pupillary response may be altered.

To test for pupil constriction, ask the patient to close his or her eyes and dim the room lights. Bring a penlight in from the side of the patient's head, and shine the light in the eye being tested as soon as the patient opens his or her eyes. The pupil being tested should constrict (**direct response**). The other pupil should also constrict slightly (**consensual response**). To test accommodation, relight the room and ask the patient to focus on a distant object and then immediately look at an object 4 to 5 inches from the nose. The eyes should converge, and the pupils should constrict.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

During a client's neurologic assessment, the nurse finds that he is arousable only if his trapezius muscle is pinched. How will the nurse document this client's level of consciousness?

- A. "Stuporous"
- B. "Lethargic"
- C. "Comatose"
- D. "Drowsy"

Psychosocial Assessment

Patients vary in their responses to a suspected or actual health problem, often depending on whether it is acute or chronic. Response is also influenced by the *mobility*, *sensory*, and/or *cognitive* impairments that temporarily or permanently result from neurologic disease or injury. For example, patients who have a mild stroke and no lasting neurologic deficits are more likely to be less depressed than patients who cannot walk as a result of spinal cord injury.

Age may also be a factor in how a patient accepts the illness. For instance, a young adult who has a motorcycle accident causing a traumatic brain injury (TBI) may react differently than an older adult who has a spinal injury. In some cases, the patient's emotional responses result from the health problem itself, especially for TBI patients.

Men may feel differently about their illness than women. Male patients who have had strokes are depressed more often than women who have had strokes. Discussions of these response differences can be found in the following chapters on specific neurologic health problems.

Regardless of what the health problem is, do not assume that everyone reacts the same way to their illness or injury. Patients experience the grieving process and may fluctuate between denial, anger, and depression. Encourage patients to express their feelings. Refer them to the appropriate support services if needed. Assess support systems, including family members and friends, if available. Document your assessment and interventions.

Diagnostic Assessment

Laboratory Assessment

For patients with a neurologic problem resulting from a systemic infection, blood cultures are necessary to identify the pathogen. Although the cause of infection must be determined for any patient, this is especially true for those with existing CNS disease. The blood-brain barrier is often not intact in neurologic disease, and the patient is more likely to get an infection of the nervous system, such as meningitis or encephalitis.

Imaging Assessment

Plain X-Rays. Plain *x-rays* of the skull and spine are used to determine bony fractures, curvatures, bone erosion, bone dislocation, and possible calcification of soft tissue, which can damage the nervous system. Several views are taken—anteroposterior, lateral, oblique, and, when necessary, special views of the facial bones. *In head trauma and multiple injuries, one of the first priorities is to rule out cervical spine fracture.*

Explain that the x-ray procedure for the skull and spine is similar to that for a chest x-ray. The patient must remain still during the procedure. Remind him or her that the exposure to radiation is minimal. If the patient is in traction and a portable x-ray unit is not available, the nurse may need to accompany him or her to assist with positioning. Any patient who cannot walk from a wheelchair to the x-ray table should be transferred to the radiology department on a stretcher. The patient is positioned for each of the desired views and is asked to not move just before each x-ray. Follow-up care is not required.

Cerebral Angiography. **Cerebral angiography (arteriography)** is done to visualize the cerebral circulation to detect blockages in the arteries or veins in the brain, head, or neck. It is not done as often today because of more recent advances in technology. A contrast medium is injected into an artery (usually the femoral) to identify aneurysms, traumatic injuries, strictures/occlusions, tumors, blood vessel displacement from edema, and arteriovenous (AV) malformations. **Chart 43-5** lists the precautions that must be taken for patients having any test using an iodine-based contrast agent. **Table 43-4** describes patient preparation and follow-up nursing care for cerebral angiography and other imaging tests.

The patient is placed on an examining table and made as comfortable as possible. At this time, dentures and hearing aids must be removed. He or she is then connected to cardiac monitoring throughout the procedure. Sedation is usually not used, although the patient may be given medication for relaxation.

The interventional radiologist or other specially trained physician numbs an area at the groin and inserts a catheter into the femoral artery. Under fluoroscopic guidance, the catheter is advanced into a carotid or vertebral artery. Then the physician injects iodinated contrast material into each vessel while recording images from different angles over the head and neck. After all the vessels have been imaged, the radiologist reviews all the images and consults with the referring physician to decide whether the patient could benefit from any therapeutic radiologic procedure to treat the problem. An arterial closure device is typically used to seal the artery and prevent bleeding.

The x-ray images are stored on a computer. With older equipment, a two-dimension or picture of the vessels is

TABLE 43-4 PREPARATION AND FOLLOW-UP FOR SELECTED DIAGNOSTIC PROCEDURES

TEST	PATIENT CARE PREPARATION	PATIENT CARE FOLLOW-UP
Cerebral angiography	Determine whether the patient is allergic to iodinated contrast agents, and follow the guideline in Chart 43-5. Ensure that the patient is NPO 4 to 6 hours before the test. Reinforce these important points: - Your head is immobilized during the procedure. - Do not move during the procedure. - You will feel a warm or hot sensation when the dye is injected—this is normal. - You will be able to talk to the physician—let him or her know if you are in pain or have any concerns. Assess and document neurologic signs, vital signs, and neurovascular checks.	Follow agency policy regarding care of the injection site, which may include: - Check dressing for bleeding and swelling around site. - Apply ice pack to site. - Keep the extremity straight and immobilized. - Maintain pressure dressing for 2 hours. Check the extremity for adequate circulation to include skin color and temperature, pulses distal to the injection site, and capillary refill. If bleeding is present, maintain manual pressure on the site and notify the physician immediately. Assess vital signs and “neuro” signs per orders. Increase oral or IV fluid intake unless contraindicated. Document assessments and interventions. Monitor the patient for a delayed allergic response if contrast medium was used.
Computed tomography (CT) 3-Dimensional CT scan CT angiography Xenon CT Intrathecal contrast-enhanced CT	Follow the guidelines listed in Chart 43-5 if a contrast agent is to be given. Determine whether the patient is claustrophobic and whether a closed CT scan is used. Inform the radiology staff or physician to determine if pre-procedure sedation is necessary. Instruct the patient to remove hairpins, hairpieces, or wigs. Inform the patient that the scanner may make noise or knocking sounds. Reassure the patient that he or she will be able to communicate with the technician throughout the procedure. If contrast is used, the patient may feel a warm or cool sensation after the dye is injected. Occasionally the patient may report a slight metallic taste. A lumbar puncture is performed before an intrathecal contrast-enhanced CT.	The radioisotope is eliminated in the urine; no special precautions required. Encourage the patient to increase fluid intake unless contraindicated.
Positron emission tomography (PET)	Follow preparation as listed for CT. Instruct the patient to withhold caffeine, alcohol, and tobacco for 24 hours before the test. Ensure that the patient has been NPO status for 4 to 12 hours before the procedure (if the patient is diabetic, no insulin is given before the test). Do not give any glucose solutions and any other drugs that alter glucose metabolism. Insert two IV lines.	The patient can return to his or her previous activity level.
Single-photon emission computed tomography (SPECT)	Patient preparation is similar to that for PET/CT. Determine whether the patient has recently had other nuclear medicine screenings, which may leave traces of the radiopharmaceutical agent. Follow the guidelines listed in Chart 43-5 regarding use of a contrast agent.	No special postprocedure or follow-up care is required.
Magnetic resonance imaging (MRI) Magnetic resonance angiography (MRA) Magnetic resonance spectroscopy (MRS)	Follow the information for CT scan. No metal objects may enter the MRI room. Ask the patient about any metal implants including any type of pacemaker device, implantable pumps, or stimulating devices. Instruct the patient to remove all metal objects (jewelry, earrings, body piercings, hairpins, watches, rings, pens). Check with the radiologist regarding tattoos. Do not enter the MRI room unless you have checked with the radiology technician and are sure that neither you nor the patient has any metal device. Ensure all equipment and supplies are free of metal.	Obtain vital signs and complete neurologic checks. Follow agency policy regarding bedrest and remaining flat. Encourage the patient to increase fluid intake unless contraindicated. Monitor for complications, especially increased intracranial pressure (severe headache, nausea, vomiting, photophobia, change in level of consciousness). Observe the needle insertion site for leakage. Notify the physician if it occurs. Provide drug for headache. Notify the physician if drug does not relieve pain.
Lumbar puncture	Explain the procedure, noting that some discomfort may be felt when the local anesthetic is injected or that pain may occur in the leg(s) when the spinal needle is inserted. Place the patient in the fetal position, and remind him or her to remain still. If needed, keep the patient from moving.	

CHART 43-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Precautions for the Injection of Iodine-Based Contrast Agent for Diagnostic Testing**

Special precautions are taken for patients who will receive a contrast agent as part of their diagnostic test. These measures include:

- Following agency guidelines regarding informed consent
- Determining whether the patient has any food or fluid restrictions before the test
- Asking the patient about allergies to contrast agents, shellfish, or iodine
- Determining risk factors for contrast-induced nephropathy (renal damage):
 - Pre-existing renal disease
 - Diabetic nephropathy
 - Heart failure
 - Dehydration

Assess for drugs that interfere with renal perfusion, such as metformin. Interventions include:

- Notifying the health care provider if the patient has reported a risk factor
- Checking the patient's creatinine level (Patients with a level greater than 1.5 mg/dL are more at risk for contrast-induced nephropathy.) Notifying the patient's health care provider of results
- Documenting the date, time, and name of the physician or nurse practitioner notified of the potential allergy and what actions he or she prescribed, if any

produced. Most radiographic systems now come with software to create three-dimensional images of the blood vessels in the head and/or neck. These systems can also display a “subtracted image” made from two images—one just before the contrast was injected and one with the contrast in the artery. The risks of the procedure are contrast reaction (including hives and flushing), thrombosis (clotting), and bleeding from the entry site. Patients with known contrast sensitivity are pre-treated with steroids.

Computed Tomography. Computed tomography (CT) scanning is an accurate, quick, easy, noninvasive, painless, and least expensive method of diagnosing neurologic problems (see [Chart 43-5](#) and [Table 43-4](#)). With the aid of a computer, pictures are taken at many horizontal levels, or slices, of the brain or spinal cord. The cross-sectional slices build up three-dimensional pictures of the brain or spinal cord. A contrast medium may be used to enhance the image. CT scans distinguish bone, soft tissue (e.g., the brain, vascular system, and ventricular system), and fluids such as cerebrospinal fluid (CSF) or blood. Tumors, infarctions, hemorrhage, hydrocephalus, and bone malformations can also be identified. A CT scan may be performed after a myelogram. (See [Chapter 52](#) for a brief discussion of this test.)

The patient is placed on a movable table in a head-holding device. He or she must remain completely still during the test, which may be difficult. The table is positioned in the machine—a large, donut-shaped structure. Depending on the scan, the patient may be completely enclosed or in a more open situation. A noncontrast series of pictures are taken first. Then, if needed, the patient is withdrawn from the scanner and given an injection of the iodinated contrast medium. The scan is then repeated. Each set of head scans takes less than 5 minutes in newer scanners. Spinal studies

take about 10 minutes per body section (cervical, thoracic, lumbar) and are less likely to require contrast injection.

Most patients with new neurologic symptoms have both a pre-contrast and post-contrast study of the head. Contrast-enhanced CT is especially useful in locating and identifying tumor types and abscesses. For situations in which bleeding is the only concern (e.g., in trauma patients), contrast scans are not usually required.

After a standard CT scan, imaging software digitally removes images of soft tissue so that only images of bone remain. Through the use of this technology, bone deformities, trauma, and birth defects are more easily identified.

CT angiography involves administering contrast dye IV before the CT scan. It is used to identify blockages or narrowing of blood vessels, aneurysms, and other blood vessel abnormalities.

Xenon computed tomography is performed to evaluate blood flow to brain tissue. The patient breathes xenon, a colorless, odorless gas, while undergoing a standard CT scan.

An intrathecal contrast-enhanced CT scan is performed to diagnose disorders of the spine and spinal nerve roots. A lumbar puncture is performed so that a small amount of spinal fluid can be removed and mixed with contrast dye and injected. The patient is positioned to allow for the contrast medium to move around the spinal cord and nerve roots as needed. The patient may have a headache after the procedure. Follow facility policy regarding patient positioning after the procedure.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) produces images that are better than the CT scan. It does not use ionizing radiation but, instead, relies on magnetic fields. Multiple sets of images are taken that are used to determine normal and abnormal anatomy. Images may be enhanced with the use of gadolinium, a non-iodine-based contrast medium. MRIs of the spine have largely replaced CT scans and myelography for evaluation. Some facilities have a *functional MRI (fMRI)* machine that can assess blood flow to the brain rather than merely show its anatomical structure.

In addition to the traditional MRI, a *magnetic resonance angiography (MRA)*, *magnetic resonance spectroscopy (MRS)* or *diffusion imaging (DI)* may be requested. MRA is used to evaluate blood flow and blood vessel abnormalities such as an arterial blockage, intracranial aneurysms, and AV malformations. MRS is used to detect abnormalities in the brain's biochemical processes, such as that which occurs in epilepsy, Alzheimer's disease, and brain attack (stroke). DI uses MRI techniques to evaluate ischemia in the brain to determine the location and severity of a stroke.

Newer, open-sided units (“open MRI”) now produce adequate images for those patients who do not want standard MRI scanners. MRI has been contraindicated for patients with cardiac pacemakers, other implanted pumps or devices, and ion-containing metal aneurysm clips. However, extensive trials are testing ways to safely scan some patients with pacemakers. Other implanted devices, such as vascular stents, intravascular catheter (IVC) filters, and metal vascular embolic devices, may be scanned immediately or after a certain period of time, depending on manufacturers' recommendations. MRI may also be contraindicated in patients who are confused or agitated, have unstable vital signs, are on continuous life support, or have older tattoos (which contain

lead). New physiologic monitoring systems made specifically for the scanner allow some patients who are unstable to be scanned. A comprehensive online list of medical devices tested for MRI safety and compatibility can be found at www.mrisafety.com. Medical personnel must remove any medical devices they are carrying or wearing and ensure that only approved devices are allowed in the MRI room (see Table 43-4).

Positron Emission Tomography. Positron emission tomography (PET) is a diagnostic tool that is not available in all medical centers (see Table 43-4). Its benefit over a CT scan or MRI is that it provides information about the *function* of the brain, specifically glucose and oxygen metabolism and cerebral blood flow. Current CT scanners provide information about the *structure* of the central nervous system (CNS). The newest PET machines are combination CT-PET scanners that fuse images together to produce better information about the type and location of brain dysfunction.

The physician or nuclear medicine technologist injects the patient with IV deoxyglucose, which is tagged to an isotope. The isotope emits activity in the form of positrons, which are scanned and converted into a color image by computer. The more active a given part of the brain, the greater the glucose uptake. This test is used to evaluate drug metabolism and detect areas of metabolic alteration that occur in dementia, epilepsy, psychiatric and degenerative disorders, neoplasms, and Alzheimer's disease. The level of radiation is equivalent to that of five or six x-rays but much less than exposure during CT.

Teach the patient that he or she will be NPO the night before morning testing and 4 hours before afternoon testing. Patients with diabetes have their test in the morning before taking their antidiabetic drugs. During this 2- to 3-hour procedure, the patient may be blindfolded and have earplugs inserted for all or part of the test. He or she is asked to perform certain mental functions to activate different areas of the brain. Older adults and patients with mental health/behavioral health problems may be too anxious to have a PET scan.

Single-Photon Emission Computed Tomography. The limitation of PET may be overcome through the use of **single-photon emission computed tomography (SPECT)**. This test uses a radiopharmaceutical agent that enables radioisotopes to cross the blood-brain barrier. The agent is administered by IV injection. Gamma-emitting radionuclides have longer half-lives, therefore eliminating the need for a cyclotron near the scanner. Although SPECT is less expensive than PET, the resolution of the images is limited. SPECT is particularly useful in studying cerebral blood flow, amnesia, neoplasms, head trauma, persistent vegetative state, or brain death. The test is contraindicated in women who are breastfeeding (see Table 43-4).

The patient is injected with the material about 1 hour before the actual scan by the radiologist, certified nuclear medicine technologist, or specially trained RN. The patient is positioned on an x-ray table in a quiet dark room for the actual scans. Several gamma cameras scan his or her head. When completed, the images are downloaded to a computer.

Magnetoencephalography. **Magnetoencephalography (MEG)** is a noninvasive imaging technique used to measure the magnetic fields produced by electrical activity in the brain

via extremely sensitive devices such as superconducting quantum interference devices (SQUIDS). MEG is somewhat similar to electroencephalography (EEG). The advantage is greater accuracy because of the minimal distortion of the signal. This allows for more usable and reliable localization of brain function. The brain can be observed “in action” rather than just viewing a still MRI image. These machines are not widely available because of their extremely high cost.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client with possible Alzheimer's disease is scheduled to have a positron emission tomography (PET) scan. The daughter asks the nurse how this test is different from a CT scan. What is the nurse's best response?

- A. “The PET scan is a newer test that can see the brain more clearly.”
- B. “The PET scan provides information about brain function rather than structure.”
- C. “The CT scan makes a lot of noise and the PET scan is quieter.”
- D. “The CT scan requires a contrast medium to be injected and the PET scan does not.”

Other Diagnostic Assessment

Electromyography. Electromyography (EMG) is used to identify nerve and muscle disorders as well as spinal cord disease. (See Chapter 46 for a description of patient preparation, procedure, and follow-up care.) Electromyography and electroneurography or nerve conduction velocity studies (NCVs) are usually used together and are referred to as *electromyoneurography*.

Electroencephalography. **Electroencephalography (EEG)** records the electrical activity of the cerebral hemispheres (Chart 43-6). Each graphic recording represents the voltage changes in various areas of the brain (determined by recording the difference between two electrodes). The EEG may be normal even when a pathologic condition is present. Brain electrical activity has certain frequencies (the number

CHART 43-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

The Patient Having an Electroencephalogram

- Thoroughly explain the procedure to the patient.
- If the order is for the patient to be “sleep deprived,” remind the patient to wake up about 2 to 3 AM and to stay awake for the rest of the night.
- Instruct the patient to avoid central nervous system depressants or stimulants. Withhold anticonvulsants only if instructed by the physician. Monitor the patient carefully for seizures if medication is withheld.
- Instruct the patient to not drink caffeine-containing fluids, such as coffee or tea, on the day of the test.
- Reassure the patient that the test is not dangerous or uncomfortable.
- Ask the patient to wash his or her hair on the morning of the test. Instruct the patient not to apply sprays or oils after the hair has been washed. The patient should remove all hairpins, ribbons, and other hair accessories.
- Inform the patient that he or she will need to wash the hair after the test to remove the electrode glue.

of waves per second) that are normal for different levels of consciousness. Brain waves are faster when the patient is awake and slower when the patient is asleep. There are normal patterns to the waves, and the neurologist looks for the frequencies and patterns. The test is performed to:

- Determine the general activity of the cerebral hemispheres
- Determine the origin of seizure activity (epilepsy)
- Determine cerebral function in pathologic conditions other than epilepsy, such as tumors, abscesses, cerebrovascular disease, hematomas, injury, metabolic diseases, degenerative brain disease, and drug intoxication
- Differentiate between organic and hysterical or feigned blindness or deafness
- Monitor cerebral activity during surgical anesthesia
- Diagnose sleep disorders (all-night EEG)
- Determine brain death

Abnormal results on an EEG test may be due to:

- An abnormal structure in the brain, such as a brain tumor
- Attention problems
- Tissue death due to a blockage in blood flow (cerebral infarction)
- Drug or alcohol abuse
- Head injury
- Inflammation of the brain (encephalitis)
- Hemorrhage (abnormal bleeding caused by a ruptured vessel)
- Migraine headaches
- Seizure disorder
- Sleep disorder

The patient is placed on a reclining chair or bed. According to an internationally accepted procedure, 16 to 24 electrodes are usually attached to the scalp with a jelly-like substance and connected to the machine. The physician or EEG technician places glue over the electrodes to prevent slippage. The patient must lie still with his or her eyes closed during the initial recording. The rest of the test engages the patient in certain activities: hyperventilation, photic stimulation, and sleep. A portable EEG may be performed at the bedside if necessary, but the preference is for the EEG to be done in a very quiet room.

Hyperventilation produces cerebral vasoconstriction and alkalosis, which increases the likelihood of seizure activity. The patient is asked to breathe deeply 20 to 30 times for 3 minutes. In *photic stimulation*, a strobe light (bright light) is placed in front of the patient. Frequencies of 1 to 20 flashes per second are used with the patient's eyes open and then closed. If the patient's seizures are photosensitive in origin, the EEG will show waves corresponding to each flash of light or waves indicating seizure activity. *Sleep* is either natural or induced by an oral or IV sedative. EEG waves indicative of temporal lobe epilepsy can be demonstrated best during sleep.

Throughout the test, which takes 40 to 60 minutes, the technician watches the patient closely and records any movement. These movements alter the record and must be labeled as artifacts. Examples of artifacts are tongue movement, eye blinking, muscle tenseness, and nervousness.

Evoked Potentials. *Evoked potentials* (also called *evoked response*) measure the electrical signals to the brain generated by hearing, touch, or sight. These tests are used to assess sensory nerve problems and confirm neurologic conditions

including multiple sclerosis, brain tumor, acoustic neuroma (small tumors of the inner ear), and spinal cord injury. Evoked potentials are also used to test sight and hearing (especially in infants and young children), monitor brain activity in coma patients, and confirm brain death.

One set of electrodes is attached to the patient's scalp using conducting paste, and the second set is attached to the part of the body to be tested. A stimulus is applied, and the amount of time it takes for the impulse generated by the stimulus to reach the brain is recorded. Under normal circumstances, the process of signal transmission is instantaneous.

Auditory evoked potentials (also called *brainstem auditory evoked response*) are used to assess high-frequency hearing loss, diagnose any damage to the acoustic nerve and auditory pathways in the brainstem, and detect acoustic neuromas. The patient sits in a soundproof room and wears headphones. Clicking sounds are delivered one at a time to one ear while a masking sound is sent to the other ear.

Visual evoked potentials detect loss of vision from optic nerve damage (in particular, damage caused by multiple sclerosis). The patient sits close to a screen and is asked to focus on the center of a shifting checkerboard pattern. Only one eye is tested at a time. The other eye is either kept closed or covered with a patch.

Somatosensory evoked potentials measure response from stimuli to the peripheral nerves and can detect nerve or spinal cord damage or nerve degeneration from multiple sclerosis and other degenerating diseases. Tiny electrical shocks are delivered by electrode to a nerve in an arm or leg.

Cerebral Blood Flow Evaluation. *Cerebral blood flow (CBF)* can be measured in many areas of the brain with the use of radioactive substances. It is particularly useful in evaluating cerebral vasospasm. Explain the test, and ask the physician if central nervous system (CNS) depressants and stimulants should be withheld for 24 hours before the test.

Because *xenon* readily diffuses into brain tissue, it is the most common choice as an inhaled or injected tracer. The xenon travels through the vessels of the brain, where it is detected by external scintillation counters placed on the skull. Normal CBF is 50 to 55 mm/min/100 g of cerebral tissue. The patient receives various stimuli during the test. Increases in local blood flow can be seen with any neuronal activity, such as reading, hand movement, seizures, and temperature elevation (up to 107.6° F [42° C]). Local blood flow decreases with neurodegenerative disease, comas of metabolic origin, increased intracranial pressure (ICP), or subarachnoid hemorrhage. Follow-up care for this test is not required.

Lumbar Puncture. *Lumbar puncture (spinal tap)* is the insertion of a spinal needle into the subarachnoid space between the third and fourth (sometimes the fourth and fifth) lumbar vertebrae (see Table 43-4).

A lumbar puncture (LP) is used to:

- Obtain cerebrospinal fluid (CSF) pressure readings with a manometer
- Obtain CSF for analysis
- Check for spinal blockage caused by a spinal cord lesion
- Inject contrast medium or air for diagnostic study
- Inject spinal anesthetics
- Inject selected drugs

Because of the danger of sudden release of CSF pressure, a lumbar puncture is not done for patients with symptoms indicating severely increased ICP. The procedure is also not

performed in patients with skin infections at or near the puncture site because of the danger of introducing infective organisms into the CSF.

Before an LP is performed, position the patient in a fetal side-lying position to separate the vertebrae and move the spinal nerve roots away from the area to be accessed. The health care provider then cleans the skin site thoroughly. The injection site is determined, and a local anesthetic is injected. In a few minutes, a spinal needle is inserted between

the third and fourth lumbar vertebrae. Instruct the patient to inform the provider if there is shooting pain or a tingling sensation. After determining proper placement in the subarachnoid space by removing the stylet and seeing CSF, the patient is asked to relax as much as possible so the pressure reading will be accurate. Opening and closing pressure readings are taken and recorded. Three to five test tubes of CSF are usually collected and numbered sequentially. After specimen collection, the needle is withdrawn, slight pressure is

TABLE 43-5 SIGNIFICANCE OF CEREBROSPINAL FLUID FINDINGS

FINDINGS	SIGNIFICANCE
Pressure	
More than 20 cm H ₂ O	Indicates increased spinal pressure, most often from bleeding, tumors, or infection within the CNS
Color/Appearance	
Clear, colorless	Normal
Pink-red to orange	Red blood cells present
Yellow	Bilirubin present owing to hemolysis of red blood cells; possible causes include subarachnoid hemorrhage, jaundice, increased cerebrospinal fluid (CSF) protein, hypercarotenemia, or hemoglobinemia
Brown	Methemoglobin present, indicating previous meningeal hemorrhage
Unclear or hazy	Cell count is elevated
Cells	
0-5 small lymphocytes/mm ³	Normal
More than 5 lymphocytes/mm ³	Reaction to infection, tumor, chemical substance, or blood
Proteins	
Total	
15-45 mg/dL (<i>up to 70 mg/dL in older adults</i>)	Normal
45-100 mg/dL	Paraventricular tumor
50-200 mg/dL	Viral infection
More than 500 mg/dL	Bacterial infection, Guillain-Barré syndrome
Less than 15 mg/dL	Meningismus, pseudotumor cerebri, hyperthyroidism, normal finding after lumbar puncture
Immune Gamma Globulin (IgG, the most important protein)	
3%-12% of total protein	Normal
More than 12% of total protein	Multiple sclerosis, neurosyphilis, or viral infection
Albumin/Globulin Ratio	
8:1	Normal
Glucose	
50-75 mg/dL or 60%-70% of blood glucose level	Normal
Less than 50 mg/dL (usually accompanied by the presence of pathologic organisms)	Bacterial, fungal, or viral meningitis; central nervous system (CNS) leukemia; or cancer
Other Characteristics	
Lactic Acid	
10-25 mg/dL	Normal
More than 25 mg/dL	Systemic acidosis or increased CSF glucose metabolism
Glutamine	
6-15 mg/dL	Normal
More than 15 mg/dL	Hepatic coma or cirrhosis of liver
Lactate Dehydrogenase	
10% of serum level or 2.0-7.2 units/mL	Normal
More than 10% of serum level	Bacterial meningitis, inflammatory diseases of CNS

applied, and an adhesive bandage strip is placed over the insertion site.

NURSING SAFETY PRIORITY

Action Alert

Be sure that the patient does not move during a lumbar puncture. If the patient is restless or cannot cooperate, two people may need to assist instead of one. Consider this possibility before beginning the procedure.

Examination of CSF has been a useful diagnostic tool for some time. Recent technical advances are increasing the number of analyses that can be done on CSF. The normal characteristics of CSF and some of the more common abnormalities are given in Table 43-5. Gram-stain smears can test for particular types of meningitis, such as tubercular meningitis. CSF can be cultured, and sensitivity studies determine the best choice of antibiotic if an infection is diagnosed. A specific test for neurosyphilis is the fluorescent treponemal antibody absorption (FTA-ABS) test. Cytologic studies of CSF can identify tumor cells.

Complications of lumbar puncture, although not common, include brainstem herniation (discussed in Chapter 47), infection, CSF leakage, and hematoma formation.

Transcranial Doppler Ultrasonography. Intracranial hemodynamics can be evaluated through the use of the transcranial Doppler (TCD). It uses sound waves to measure blood flow through the arteries. The test is particularly valuable in evaluating cerebral vasospasm or narrowing of arteries. TCD is safe, can be used repeatedly for the same patient, and is an inexpensive alternative to angiography.

Muscle and Nerve Biopsies. Muscle or nerve biopsies are used to diagnose neuromuscular disorders. They may also reveal if a person is a carrier of a defective gene that could be passed on to children. Under local anesthesia, an incision is made into the skin or a hollow needle is inserted through the skin to remove a small sample of muscle or nerve. A CT scan or MRI is performed before a *brain biopsy*. This procedure involves injection of a local anesthetic into the scalp, drilling a small hole through the skull, and inserting a hollow needle into the site of the lesion. Muscle, nerve, and brain biopsy samples are analyzed under a microscope to identify abnormalities.

NURSING CONCEPT REVIEW

What should you NOTICE in a patient with adequate mobility, sensation, and cognition?

Physical assessment

- Alert and oriented
- Vital signs within normal limits
- Pupils equal in size, round and regular in shape, and reactive to light and accommodation (PERRLA)
- Moves all four extremities without assistance
- Walks, with or without assistive devices, using normal gait

- No deficits in or unusual sensation
- No loss of memory and attention
- Communicates clearly
- Can perform ADLs independently

Diagnostic assessment

- Normal CSF
- Normal electroencephalogram (EEG)
- Normal CT scan of brain
- Normal MRI scan of spinal cord

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for older adults, remind them to move slowly and use caution when ambulating. Older adults have an altered balance and decreased coordination (see Chart 43-1).
- For tests that use iodine-based contrast media, use precautions as listed in Chart 43-5.
- Check for bleeding after patients have an angiography. If bleeding is observed, call the radiologist immediately.
- Before MRI, check for devices such as pacemakers, vascular stents, implanted pumps, and aneurysm clips.

Health Promotion and Maintenance

- Reinforce teaching and use teaching aids for older adults who typically have recent memory loss.
- Explain what patients should expect before diagnostic testing for neurologic structure and function.
- Encourage patients who receive contrast media or isotopes to push fluids to increase elimination of the material.
- Teach patients having an EEG to follow the precautions listed in Chart 43-6.

Psychosocial Integrity

- Assess the mental status of patients as part of the neurologic assessment, including orientation.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Remember that a change in level of consciousness (LOC) is the first indicator of neurologic decline.
- Assess the patient's reaction to the neurologic disease or injury.
- Assess the patient's memory, because loss of memory, especially recent memory, tends to be an early sign of neurologic problems.
- Check pupils for size, shape, and reaction. Pupils should be equal in size, round and regular in shape, and reactive to light and accommodation.
- Be aware that decerebrate or decorticate posturing and pinpoint or dilated nonreactive pupils are late signs of neurologic deterioration.
- Provide pre-test and post-test nursing care for patients having neurologic diagnostic testing, as outlined in [Table 43-4](#).

Physiological Integrity

- Take a patient history, including information listed in [Charts 43-2 and 43-3](#).
- Evaluate the patient's sensory and motor abilities, as well as gait, balance, and coordination.
- Use the Glasgow Coma Scale as one measure of neurologic functioning—the lower the score, the poorer the function. Assess for mental status changes (see [Chart 43-4](#)).
- Follow best practice guidelines in [Chart 43-6](#) when caring for a patient having an EEG.
- Assist with patient positioning during a lumbar puncture (fetal position preferred).
- Recall that normal cerebrospinal fluid (CSF) is clear and colorless with few cells.

Care of Patients with Problems of the Central Nervous System: The Brain

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Plan health teaching for hospital discharge to home or other setting for patients with chronic problems of the brain.
2. Collaborate with interdisciplinary health care team members when caring for older adults with Parkinson disease (PD) and Alzheimer's disease (AD).
3. Implement interventions to protect patients with AD, PD, and seizures from injury.

Health Promotion and Maintenance

4. Teach patients with chronic headaches about complementary and alternative therapies.
5. Teach patients in highly populated areas ways to prevent meningitis.
6. Teach patients and their families about credible resources for genetic testing and counseling for types of chronic brain disorders that are known to be hereditary.
7. Identify community resources for patients with PD and AD.

Psychosocial Integrity

8. Include the family when culturally appropriate in developing the plan of care for patients with chronic brain disorders.
9. Identify ways to help prevent caregiver stress when caring for patients with AD and other chronic neurodegenerative diseases.
10. Adapt communication techniques for patients with dementia, including validation therapy.

Physiological Integrity

11. Identify triggers for patients with chronic headaches.
12. Compare the assessment findings of migraine, cluster, and tension headaches.
13. Prioritize care for patients with migraine headaches.
14. Differentiate the common types of seizures, including presenting clinical manifestations.
15. Prioritize care for patients experiencing acute seizures and status epilepticus.
16. Describe collaborative care for a patient having a seizure.
17. Implement seizure precautions for patients at risk for acute seizures or status epilepticus.
18. Identify nursing priorities for patients with bacterial meningitis and encephalitis.
19. Describe abnormal neurologic findings in patients with chronic brain problems.
20. Identify the genetic and environmental influences on development of PD, AD, and Huntington disease.
21. Develop a community-based plan of care for a patient with PD and AD.
22. Provide health teaching for patients and family about drug therapy for patients with chronic brain problems.
23. Develop a collaborative plan of care for patients with AD.
24. Prevent or reduce common risk factors that contribute to functional decline and decreased quality of life in older adults with PD and AD.
25. Develop a teaching plan for caregivers of patients with AD.
26. Identify the need for genetic counseling for patients who have Huntington disease.

The brain is part of the central nervous system (CNS) that functions as the body's center for controlling mobility (movement), sensation, and cognition. Health problems involving damage of the brain can be acute or chronic. These problems often affect the patient's level of independence and quality of life. This chapter discusses acute CNS infections and common *chronic* neurodegenerative diseases of the brain that may impair a person's needs for *mobility* and *cognition*. Care of patients with chronic disorders requires coordination by nurses and other members of the interdisciplinary health care team. The patient and family are the center of the collaborative team in making decisions about the plan of care.

HEADACHES

Almost everyone has had a headache at some time in his or her life. Some headaches are related to "colds," allergies, or stress and are temporary. Others can be very serious and potentially life threatening. For example, an abnormal neurologic assessment together with symptoms of a cluster headache may indicate a serious neurologic problem. Patients with these symptoms are referred immediately to their health care provider or the emergency department.

Although there are many types and causes of headaches, the focus of this section is on two common types that cause people to seek medical attention: migraine headaches and cluster headaches. Patients are usually managed in the ambulatory care setting by the primary health care provider. However, it is not unusual for the person in severe pain to seek treatment in the emergency department.

As part of the nursing assessment, ask patients about the pattern of their headaches. For example:

- When do the headaches occur?
- How often?
- How long do they last?
- Do certain foods, alcohol, or other things trigger the headaches?
- Have there been any recent changes in your headaches?
- How do you treat the headaches? Does this treatment work?
- How often and what drug or herbal remedy do you take?

Other questions include:

- Is there a family history of headaches?
- Where do the headaches begin? Do they spread to other areas?
- Do you experience other symptoms with the headaches, such as weakness or changes in speech?
- How does this impact your activities of daily living?

! NURSING SAFETY PRIORITY

Action Alert

Encourage patients to keep a headache diary, which may help identify the type of headache they are experiencing. Teach them to notify their health care provider if the quality, intensity, or nature of the headache increases or changes. Encourage them to report whether the headache is associated with unusual visual changes and whether the prescribed drug is no longer effective.

MIGRAINE HEADACHE

Pathophysiology

A **migraine headache** is a chronic, episodic disorder with multiple subtypes. It is characterized by an intense pain in one side of the head (unilateral) worsening with movement and occurs with either photophobia (sensitive to light) or phonophobia (sensitive to noise). Either moderate to severe nausea or vomiting is also present (McCance et al., 2010). A migraine is classified as a *long-duration headache* because it usually lasts 4 to 72 hours.

Migraines tend to be familial, and women are affected more commonly than men. Women with anxiety and depressive personalities are particularly predisposed to migraines and other chronic health problems (Tan et al., 2007). Migraine sufferers are also at risk for stroke and epilepsy (McCance et al., 2010).

The cause of migraine headaches is likely a combination of vascular, genetic, neurologic, hormonal, and environmental factors. It is generally agreed that migraine headaches are mediated via the trigeminal vascular system and its central projections. Blood vessels in the brain overreact to a triggering event, causing spasm in the arteries at the base of the brain. This response is followed by arterial constriction and a decrease in cerebral blood flow. Cerebral hypoxia may occur. Platelets clump together, and serotonin, a vasoconstrictor, is released. Other arteries dilate, which triggers the release of **prostaglandins** (chemicals that cause inflammation and swelling) and other substances that increase sensitivity to pain. Research suggests a role of excessive synaptic glutamate release or decreased removal of glutamate and potassium from the synaptic cleft (Sanchez-del-Rio et al., 2006).

Many patients find that certain factors, or *triggers*, such as caffeine, red wine, stress, and monosodium glutamate (MSG) tend to cause migraine headache attacks. Each patient is different regarding which environmental factors trigger headaches. For some patients, being stressed or a change in weather can lead to an attack.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Migraines fall into three categories: migraines with aura, migraines without aura, and atypical migraines. An **aura** is a sensation such as visual changes that signals the onset of a headache or seizure. In a migraine, the aura occurs immediately before the migraine episode. *Most headaches are migraines without aura.* The key features of migraines are listed in **Chart 44-1**. **Atypical migraines** are less common and include menstrual and cluster migraines. The stages of migraine may include:

- Prodrôme (or prodromal) phase, in which the patient has specific symptoms such as food cravings or mood changes
- Aura phase (if present), which generally involves visual changes, flashing lights, or **diplopia** (double vision)
- Headache phase, which may last a few hours to a few days
- Termination phase, in which the intensity of the headache decreases

CHART 44-1 KEY FEATURES

Migraine Headaches**Phases of Migraine with Aura (Classic Migraine)****First, or Prodrome, Phase**

- Aura develops over a period of several minutes and lasts no longer than 1 hour.
- Well-defined transient focal neurologic dysfunction exists.
- Pain may be preceded by:
 - Visual disturbances
 - Flashing lights
 - Lines or spots
 - Shimmering or zigzag lights
- Pain may be preceded by a variety of neurologic changes, including:
 - Numbness, tingling of the lips or tongue
 - Acute confusional state
 - Aphasia
 - Vertigo
 - Unilateral weakness
 - Drowsiness

Second Phase

- Headache is accompanied by nausea and vomiting.
- Pain usually begins in the temple. It increases in intensity and becomes throbbing within 1 hour.

Third Phase

- Pain changes from throbbing to dull.
- Headache, nausea, and vomiting usually last from 4 to 72 hours. (Older patients may have aura without pain, known as a *visual migraine*.)

Migraine Without Aura (Common Migraine)

- Migraine begins without an aura before the onset of the headache.
- Pain is aggravated by performing routine physical activities.
- Pain is unilateral and pulsating.
- One of these symptoms is present:
 - Nausea and/or vomiting
 - **Photophobia** (light sensitivity)
 - **Phonophobia** (sound sensitivity)
- Headache lasts for 4 to 72 hours.
- Migraine often occurs in the early morning, during periods of stress, or in those with premenstrual tension or fluid retention.

Atypical Migraine

- Status migrainous:
 - Headache lasts longer than 72 hours.
- Migrainous infarction:
 - Neurologic symptoms are not completely reversible within 7 days.
 - Ischemic infarct is noted on neuroimaging.
- Unclassified:
 - Headache does not fulfill all of the criteria to be classified a migraine.

- Postprodrome phase, in which the patient is often fatigued, may be irritable, and has muscle pain

The diagnosis of migraine headache is based on the patient's history and on physical, neurologic, and psychological assessment. The typical migraine is described as a unilateral, fronto-temporal, *throbbing* pain in the head that is often worse behind one eye or ear. It is often accompanied by a sensitive scalp, anorexia, **photophobia** (sensitivity to light), **phonophobia** (sensitivity to noise), and nausea with or without vomiting. The pain and associated symptoms can last

from 4 to 72 hours. Patients tend to have the same clinical manifestations each time they have a migraine headache. Some may have to refrain from regular activities for several days if they cannot control or relieve the pain in its early stage.

Some physicians recommend screening migraine patients with the Minnesota Multiphasic Personality Inventory–2 to identify personality traits and possible mental health/behavioral health problems (Tan et al., 2007). Neuroimaging such as magnetic resonance imaging (MRI) may be indicated if the patient has other neurologic findings, a history of seizures, findings not consistent with a migraine, or a change in the severity of the symptoms or frequency of the attacks.

Neuroimaging is also recommended in patients older than 50 years with a new onset of headaches, especially women. Women with a history of migraines with visual symptoms may have an increased risk for stroke (McCance et al., 2010). This risk increases if a migraine with visual symptoms occurred in the past year. Teach women older than 50 years who have migraines about the risk factors for cardiovascular disease. Encourage them to notify their health care provider if they experience symptoms such as facial drooping, arm weakness, or difficulties with speech.

INTERVENTIONS

Migraine headaches are often not diagnosed or managed following current best practices. Therefore the National Headache Foundation has recommended the “Three R” approach for patients and health care providers (www.headaches.org):

- **Recognize** migraine symptoms
- **Respond** and see the health care provider
- **Relieve** pain and associated symptoms

The priority for care of the patient having migraines is pain management. This outcome may be achieved by abortive and preventive therapy. Drug therapy, trigger management, and complementary and alternative therapies are the major approaches to care. Provide detailed patient and family education regarding the collaborative plan of care.

Abortive Therapy

Abortive therapy is aimed at alleviating pain during the aura phase (if present) or soon after the headache has started. *Drug therapy* is prescribed to manage migraine headaches. Some of the drugs being used have major side effects, contraindications, and nursing implications. The health care provider must consider any other medical conditions that the patient has when prescribing drug therapy. In general, the patient is started on a low dose that is increased until the desired clinical effect is obtained. Table 44-1 lists commonly used drugs for migraine headaches. Many new drugs are being investigated for this painful and often debilitating health problem.

Mild migraines may be relieved by acetaminophen (APAP) (Tylenol, Abenol ) . NSAIDs such as ibuprofen (Motrin) and naproxen (Naprosyn) may also be prescribed. In the United States, the Food and Drug Administration (FDA) has approved several over-the-counter (OTC) anti-inflammatory drugs for migraines, including Advil Migraine Capsules, Motrin Migraine Pain Caplets, and Excedrin Migraine Tablets or Caplets (contain APAP, aspirin, and caffeine). Caffeine narrows blood vessels by blocking adenosine, which dilates vessels and increases inflammation. Antiemetics may be prescribed to relieve nausea and vomiting. Metoclopramide

TABLE 44-1 COMMONLY USED DRUGS FOR MIGRAINE HEADACHE

Nonspecific Analgesics

- Acetaminophen
- Isometheptene
- Butalbital

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

- Ibuprofen
- Naproxen

Ergotamine Preparations

- Ergotamine with caffeine (oral or suppository) (Cafergot, Migergot)
- Ergotamine sublingual (SL) (Ergomar SL)
- Medihaler ergotamine (oral inhalation aerosol)
- Dihydroergotamine (DHE) nasal spray (Migranal)

Beta Blockers

- Propranolol
- Timolol

Triptan Preparations

- Almotriptan (Axert)
- Eletriptan (Relpax)
- Rizatriptan (Maxalt)
- Zolmitriptan (Zomig)
- Sumatriptan (Imitrex)
- Frovatriptan (Frova)

Isometheptene Combination

- Midrin

Antiepileptic Drugs (AEDs)

- Divalproex (Depakote)
- Topiramate (Topamax)

(Reglan, Clopra) may be administered with NSAIDs to promote gastric emptying and decrease vomiting.

For more severe migraines, drugs such as triptan preparations, ergotamine derivatives, and isometheptene combinations are needed. A potential side effect of these drugs is **rebound headache**, also known as **medication overuse headache**, in which another headache occurs after the drug relieves the initial migraine.

Triptan preparations relieve the headache and associated symptoms by activating the 5-HT (serotonin) receptors on the cranial arteries, the basilar artery, and the blood vessels of the dura mater to produce a vasoconstrictive effect. Examples include zolmitriptan (Zomig) and eletriptan (Relpax). Sumatriptan (Imitrex) is also available in tablets, as an injection, and in a nasal spray. For many patients, these drugs are highly effective for pain, nausea, vomiting, and light and sound sensitivity with few side effects. Most are contraindicated in patients with actual or suspected ischemic heart disease, cerebrovascular ischemia, hypertension, and peripheral vascular disease and in those with Prinzmetal's angina because of the potential for coronary vasospasm. Patients respond differently to drugs, and several types or combinations may be tried before the headache is relieved.

! NURSING SAFETY PRIORITY**Drug Alert**

Teach patients taking triptan drugs to take them as soon as migraine symptoms develop. Instruct patients to report chest pain or tightness to their health care providers immediately because they may develop angina. Remind them to use contraception (birth control) while taking the drugs because the drugs may not be safe for women who are pregnant. Teach them to expect common side effects that include flushing, tingling, and a hot sensation. These annoying sensations tend to subside after the patient's body gets used to the drug. Triptan drugs should not be taken with selective serotonin reuptake inhibitor (SSRI) antidepressants or St. John's wort, an herb used commonly for depression.

Ergotamine preparations such as Cafergot are taken at the start of the headache. The patient may take up to six tablets in 24 hours or use a rectal suppository. Dihydroergotamine (DHE) may be given IV, IM, or as a nasal spray (Migranal) with an antiemetic if pain control and relief of nausea are not achieved with other drugs. DHE should not be given within 24 hours of a triptan drug.

Midrin is a combination drug containing APAP, isometheptene, and dichloralphenazone. It is the most common *isometheptene combination* given for treating migraines and is an excellent option when ergotamine preparations are not tolerated or do not work.

Other drugs that have been prescribed to relieve migraine pain include opioids and barbiturates. *These drugs should be avoided if at all possible because they are addictive. Some opioids actually cause a migraine.*

Preventive Therapy

Prevention drugs and other strategies are used when a migraine occurs more than twice per week, interferes with ADLs, or is not relieved with acute treatment. Unless otherwise contraindicated, the health care provider may initially prescribe an NSAID, a beta-adrenergic blocker, a calcium channel blocker, or an antiepileptic drug (AED). Propranolol (Inderal, Apo-Propranolol ♣, Novopropanol ♣) and timolol (Blocadren, Apo-Timol ♣) are the only *beta blockers* approved for migraine prevention. Verapamil (Calan, Apo-Verap ♣), a *calcium channel blocking agent*, may also be used for some patients. Both beta-adrenergic blockers and calcium channel blocking drugs can lower blood pressure and decrease pulse rate.

! NURSING SAFETY PRIORITY**Drug Alert**

Teach patients who take beta-adrenergic blockers and calcium channel blockers how to take their pulse. Encourage them to report bradycardia or clinical manifestations of heart failure such as fatigue and shortness of breath to their health care provider as soon as possible.

Topiramate (Topamax) is one of the most common *antiepileptic drugs (AEDs)* used for migraines, but it should be used in low doses. Reports of suicides have been associated with this drug when it is used in larger doses, most often with patients who have bipolar disorder.

In addition to drug therapy, *trigger avoidance and management* are important interventions for preventing migraine episodes. For example, some patients find that avoiding tyramine-containing products, such as pickled products, caffeine, beer, wine, preservatives, and artificial sweeteners, reduces their headaches. Others have identified specific factors that trigger an attack for them. Help patients identify triggers that could cause migraine episodes, and teach them to avoid them once identified (Chart 44-2). For example, at the beginning of a migraine attack, the patient may be able to reduce pain by lying down and darkening the room. He or she may want both eyes covered and a cool cloth on the forehead. If the patient falls asleep, he or she should remain undisturbed until awakening.

CHART 44-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Factors That May Trigger a Migraine Attack

- Teach patients to avoid the foods, medications, and other factors that may trigger a migraine attack.
- Food and beverages (tyramine-containing):
 - Alcoholic drinks: beer, wine, and hard liquor
 - Aged cheese
 - Caffeine found in beverages such as coffee, tea, cola
 - Chocolate
 - Foods with yeast such as pastry and fresh breads
 - Monosodium glutamate (MSG)
 - Nitrates (food preservatives), pickled or fermented foods
 - Nuts
 - Artificial sweeteners
 - Smoked fish
- Drugs:
 - Cimetidine (Tagamet)
 - Estrogens
 - Nitroglycerin
 - Nifedipine (Procardia, Nifed )
- Other factors:
 - Anger, conflict
 - Fatigue
 - Hormonal fluctuations, such as menstruation, pregnancy, and menopause
 - Light glare
 - Missed meals
 - Psychological stress
 - Sleep problems
 - Smells, such as tobacco smoke
 - Travel to different altitudes

Complementary and Alternative Therapies

Many patients use complementary and alternative therapies as adjuncts to drug therapy. Yoga, meditation, massage, exercise, and biofeedback are helpful in preventing or treating migraines for some patients.

Acupuncture and acupressure may be effective in relieving pain for some patients. A number of herbs are also used for headaches, both for prevention and pain management. Teach patients that all herbs and nutritional remedies should be approved by their health care provider before use because they could interact with prescribed medication. At this time,

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The nurse is preparing a teaching plan for a client with migraine headaches who is receiving propranolol (Inderal) for migraine headaches. What health teaching by the nurse is important for the client?

- “Take this drug only when you have symptoms at the beginning of a migraine headache.”
- “This drug is low dose, so you don’t have to worry about your heart rate or blood pressure.”
- “This drug will relieve the pain during the aura phase soon after a headache has started.”
- “Take this drug as prescribed every day, even when feeling well, to prevent a migraine.”

there is insufficient evidence to support any herb or natural remedy, but some patients have had positive results.

CLUSTER HEADACHE

Pathophysiology

Cluster headaches are manifested by brief (30 minutes to 2 hours), intense unilateral pain that generally occurs in the spring and fall without warning. It is classified as the *most common chronic short-duration headache* with pain lasting less than 4 hours. Also referred to as *trigeminal autonomic cephalalgia*, it is far less common than migraines. Cluster headaches typically develop in men between 20 and 50 years of age. The cause and mechanism of cluster headaches are not known but have been attributed to vasoreactivity and neurogenic inflammation (McCance et al., 2010). Neuroimaging studies suggest that cluster headaches are related to an overactive and enlarged hypothalamus.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Question the patient about prescribed drugs for both the prevention and relief of the headache, as well as OTC drugs and herbs he or she may be taking. Interventions used by the patient may include relaxation techniques, meditation, acupuncture, or massage therapies. Ask the patient to recall a typical week’s activities and any recent changes in lifestyle. Ask him or her to identify bedtimes and waking times to help assess changes in activity or lack of continuity in the sleep-wake cycle.

The pain of these unilateral (one-sided) oculotemporal or oculofrontal headaches is often described as excruciating, boring, and *nonthrobbing*. The intense pain is felt deep in and around the eye. The headaches occur at about the same time of day for about 4 to 12 weeks (hence the term *cluster*), followed by a period of remission for 9 months to a year. This episodic form is the most common, although there is a chronic, intractable form in which there may not be a remission for more than a year.

The pain may radiate to the forehead, temple, or cheek. It may also radiate, but to a lesser extent, to the ear and neck. The temporal artery may be prominent and tender. The patient often paces, walks, or sits and rocks during an attack. A cluster is the only headache type in which this behavior occurs. During periods of remission, alcohol does not cause a headache (as it does during the headache period). The onset of the pain is associated with relaxation, napping, or rapid eye movement (REM) sleep.

The headache usually occurs with:

- **Ipsilateral** (same side) tearing of the eye
- **Rhinorrhea** (“runny nose”) or congestion
- **Ptosis** (drooping eyelid)
- Eyelid edema
- Facial sweating
- **Miosis** (constriction of pupils)

The ptosis may become permanent. Assess for possible bradycardia, flushing or pallor of the face, increased intraocular pressure, and increased skin temperature. Nausea and

vomiting may also occur. The patient may become restless and agitated from the intense pain of the headache.

INTERVENTIONS

The health care provider typically prescribes some of the same types of drugs used for migraines, such as triptans, ergotamine preparations, and antiepileptic drugs (see discussion of drug therapy in the Migraine Headache section). Additional drugs include calcium channel blockers, especially verapamil (Calan), lithium, and corticosteroids. OTC capsaicin, available as a nasal spray (civamide), melatonin, and glucosamine are also used by some patients. Provide health teaching about drug therapy.

During the periods of attack, teach the patient to wear sunglasses and to sit facing away from the window to help decrease exposure to light and glare. If the health care provider prescribes oxygen, 100% oxygen via mask at 7 to 10 L/min is typically administered with the patient in a sitting position. Administer the oxygen for 15 to 30 minutes, and discontinue it when the headache is relieved. Oxygen reduces cerebral blood flow and inhibits activity of the carotid bodies, which are sensitive to oxygen levels in the body. Patients may use oxygen at home. Teach them about the precautions that must be taken when oxygen is used (see Chapter 30).

To prevent future attacks brought on by precipitating factors (bursts of anger, prolonged anticipation, excessive physical activity, and excitement), discuss their relationship to the onset of cluster headaches. Explain the need for and importance of a consistent sleep-wake cycle.

Surgical intervention may be recommended for patients with *chronic* drug-resistant cluster headaches. Invasive ambulatory care procedures, such as *percutaneous stereotactic rhizotomy* (PSR), are performed with varying success rates. Information about this procedure is found in Chapter 46 in the Trigeminal Neuralgia section. Long-term high-frequency electrical stimulation of the posterior hypothalamus, also known as *deep brain stimulation*, may reduce or eliminate pain (see discussion on p. 946 in the Parkinson Disease section). It has not been approved by the FDA but is being investigated. Both of these procedures have major complications that can cause permanent brain or nerve damage. Therefore they are done as a last resort.

SEIZURES AND EPILEPSY

Pathophysiology

A **seizure** is an abnormal, sudden, excessive, uncontrolled electrical discharge of neurons within the brain that may result in a change in level of consciousness (LOC), motor or sensory ability, and/or behavior. A single seizure may occur for no known reason. Some seizures are caused by a pathologic condition of the brain, such as a tumor. In this case, once the underlying problem is treated, the patient is often asymptomatic.

Epilepsy is defined by the National Institute of Neurological Disorders and Stroke as two or more seizures experienced by a person. It is a chronic disorder in which repeated unprovoked seizure activity occurs. It may be caused by an abnormality in electrical neuronal activity; an imbalance of neurotransmitters, especially gamma aminobutyric acid (GABA); or a combination of both (McCance et al., 2010).

Types of Seizures

The International Classification of Epileptic Seizures recognizes three broad categories of seizure disorders: generalized seizures, partial seizures, and unclassified seizures.

Six types of **generalized seizures** may occur and involve *both* cerebral hemispheres. The *tonic-clonic seizure* lasting 2 to 5 minutes begins with a **tonic** phase that causes stiffening or rigidity of the muscles, particularly of the arms and legs, and immediate loss of consciousness. **Clonic** or rhythmic jerking of all extremities follows. The patient may bite his or her tongue and may become incontinent of urine or feces. Fatigue, acute confusion, and lethargy may last up to an hour after the seizure.

Occasionally, only tonic or clonic movement may occur. A *tonic seizure* is an abrupt increase in muscle tone, loss of consciousness, and autonomic changes lasting from 30 seconds to several minutes. The *clonic seizure* lasts several minutes and causes muscle contraction and relaxation.

The *absence seizure* is more common in children and tends to run in families. It consists of brief (often just seconds) periods of loss of consciousness and blank staring as though the person is daydreaming. The patient's eyes may flutter, and **automatisms** (involuntary behaviors) such as lip smacking and picking at clothes may also occur. He or she is not aware of these behaviors. The patient returns to baseline immediately after the seizure. Left undiagnosed or untreated, the seizures may occur frequently throughout the day, interfering with school or other daily activity.

The *myoclonic seizure* causes a brief jerking or stiffening of the extremities that may occur singly or in groups. Lasting for just a few seconds, the contractions may be symmetric (both sides) or asymmetric (one side).

In an *atonic (akineti) seizure*, the patient has a sudden loss of muscle tone, lasting for seconds, followed by **postictal** (after the seizure) confusion. In most cases, these seizures cause the patient to fall, which may result in injury. This type of seizure tends to be most resistant to drug therapy.

Partial seizures, also called *focal* or *local* seizures, begin in a part of *one* cerebral hemisphere. They are further subdivided into two main classes: complex partial seizures and simple partial seizures. In addition, some partial seizures can become generalized tonic-clonic, tonic, or clonic seizures. Partial seizures are most often seen in adults and generally are less responsive to medical treatment when compared with other types.

Complex partial seizures may cause loss of consciousness (**syncop**), or "black out," for 1 to 3 minutes. Characteristic automatisms may occur as in absence seizures. The patient is unaware of the environment and may wander at the start of the seizure. In the period after the seizure, he or she may have **amnesia** (loss of memory). Because the area of the brain most often involved in this type of epilepsy is the temporal lobe,

CONSIDERATIONS FOR OLDER ADULTS

Complex partial seizures are most common among older adults (Vacca & Olson, 2007). These seizures are difficult to diagnose because symptoms appear similar to dementia, psychosis, or Alzheimer's disease (AD), especially in the **postictal stage** (after the seizure). New-onset seizures in older adults are typically associated with conditions such as hypertension, cardiac disease, diabetes mellitus, stroke, and Alzheimer's disease.

complex partial seizures are often called *psychomotor* seizures or *temporal lobe* seizures.

The patient with a *simple partial seizure* remains conscious throughout the episode. He or she often reports an **aura** (unusual sensation) before the seizure takes place. This may consist of a “*déjà vu*” (already seen) phenomenon, perception of an offensive smell, or sudden onset of pain. During the seizure, the patient may have one-sided movement of an extremity, experience unusual sensations, or have autonomic symptoms. Autonomic changes include a change in heart rate, skin flushing, and epigastric discomfort.

Unclassified, or **idiopathic**, seizures account for about half of all seizure activity. They occur for no known reason and do not fit into the generalized or partial classifications.

Etiology and Genetic Risk

Primary or **idiopathic epilepsy** is not associated with any identifiable brain lesion or other specific cause; however, genetic factors most likely play a role in its development. **Secondary seizures** result from an underlying brain lesion, most commonly a tumor or trauma. They may also be caused by:

- Metabolic disorders
- Acute alcohol withdrawal
- Electrolyte disturbances (e.g., hyperkalemia, water intoxication, hypoglycemia)
- High fever
- Stroke
- Head injury
- Substance abuse
- Heart disease

Seizures resulting from these problems are not considered epilepsy. Various risk factors can trigger a seizure, such as increased physical activity, emotional stress, excessive fatigue, alcohol or caffeine consumption, or certain foods or chemicals.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Question the patient or family about how many seizures the patient has had, how long they last, and any pattern of occurrence. Ask the patient or family to describe the seizures that the patient has had. Clinical manifestations vary depending on the type of seizure experienced, as described earlier. Ask about the presence of an aura before seizures begin (**preictal phase**). Question whether the patient is taking any prescribed drugs or herbs or has had head trauma or high fever. Assess any alcohol and/or illicit drug history. Ask about any other medical condition such as a previous stroke or hypertension.

Diagnosis is based on the history and physical examination. A variety of diagnostic tests are performed to rule out other causes of seizure activity and to confirm the diagnosis of epilepsy. Typical diagnostic tests include an electroencephalogram (EEG), computed tomography (CT) scan, MRI, or positron emission tomography (PET) scan. These tests are described in **Chapter 43**. Laboratory studies are performed to identify metabolic or other disorders that may cause or contribute to seizure activity.

INTERVENTIONS

Removing or treating the underlying condition or cause of the seizure manages *secondary* epilepsy and seizures that are not considered epileptic. *In most cases, primary epilepsy is successfully managed through drug therapy.*

Nonsurgical Management

Most seizures can be completely or almost completely controlled through the administration of **antiepileptic drugs (AEDs)**, sometimes referred to as *anticonvulsants*, for specific types of seizures.

Drug Therapy. Drug therapy is the major component of management (**Chart 44-3**). The health care provider introduces one antiepileptic drug (AED) at a time to achieve seizure control. If the chosen drug is not effective, the dosage may be increased or another drug introduced. At times, seizure control is achieved only through a combination of drugs. The dosages are adjusted to achieve therapeutic blood levels without causing major side effects.

Teach patients to take their drugs on time to maintain therapeutic blood levels and maximum effectiveness. Emphasize the importance of taking their antiseizure medications as prescribed. Instruct patients that they can build up sensitivity to the drugs as they age. If sensitivity occurs, tell them they will need to have blood levels of this drug checked frequently to adjust the dose. In some cases, the antiseizure effects of drugs can decline and will lead to an increase in seizures. Because of this potential for “drug decline and sensitivity,” patients need to keep their scheduled laboratory appointments.

Be aware of drug-drug and drug-food interactions. For instance, warfarin (Coumadin, Warfilone ) should not be given with phenytoin (Dilantin). Document side and adverse effects of the prescribed drugs, and report to the health care provider. Patients should be taught that some citrus fruits, such as grapefruit juice, can interfere with the metabolism of these drugs. This interference can raise the blood level of the drug and cause the patient to develop drug toxicity.

CONSIDERATIONS FOR OLDER ADULTS

The health care provider prescribes AEDs for the older adult that (Vacca & Olson, 2007):

- Have minimal possibility of toxicity
- Cause few side effects
- Are available in oral route for dosing
- Are easily metabolized and absorbed
- Have a long half-life with infrequent dosing to prevent missed dose
- Are readily excreted
- Require minimal protein binding, because older adults lose protein and a therapeutic dose may be toxic to them
- Cause minimal to no weight gain to prevent complications that may be associated with heart disease

Teaching for Self-Management. Provide an educational program for the patient and family (**Chart 44-4**). Ask them what they understand about the disorder, and correct any misinformation. As new information is presented, be sure that the patient and family can understand it. Refer patients and families to the Epilepsy Foundation of America (www.epilepsyfoundation.org) for more information and community support groups.

Emphasize that AEDs must not be stopped even if the seizures have stopped. Discontinuing these drugs can lead to the

CHART 44-3 COMMON EXAMPLES OF DRUG THERAPY

Antiepileptic Drugs

DRUG	INDICATION FOR USE	NURSING INTERVENTIONS
Carbamazepine (Tegretol, Tegretol-XR, Carbatrol)	Partial, generalized tonic-clonic seizures	Monitor for headache, dizziness, diplopia or blurred vision, N/V, and leukopenia. Monitor CBC. Do not crush or chew sustained-release capsules.
Clonazepam (Klonopin)	Absence, myoclonic, and akinetic seizures	Monitor results of liver function tests.
Clorazepate dipotassium	Adjunctive management of partial seizures	Give with food. Monitor blood pressure.
Diazepam (Valium, Apo- Diazepam  , lorazepam (Ativan), Diastat (diazepam rectal gel delivery system)	Status epilepticus	Monitor a irway, b reathing, c irculation (ABCs).
Divalproex (Depakote), valproic acid (Depakene)	All types of seizures	Monitor for hair loss, tremor, increased liver enzymes, bruising, and N/V. Monitor CBC, PT, PTT, and AST.
Ethosuximide (Zarontin)	Absence seizures	Watch for N/V, skin rash, lethargy, and anorexia. Monitor CBC and liver function tests. (Drug used infrequently.)
Felbamate (Felbatol)	Adjunctive therapy for intractable complex partial seizures	Note that aplastic anemia and liver failure are major sequelae of treatment. Patient must sign consent for use, acknowledging risk for aplastic anemia and liver failure. Monitor CBC. Monitor liver function tests. Watch for anorexia and weight loss.
Gabapentin (Neurontin)	Partial seizures	Watch for increased appetite and weight gain. Monitor for ataxia, irritability, dizziness, and fatigue.
Lamotrigine (Lamictal)	Partial seizures	Watch for diplopia, headaches, dizziness, drowsiness, ataxia, N/V, and life-threatening rash when given with valproic acid.
Levetiracetam (Keppra)	Adjunct management of partial seizures	Monitor renal function carefully. Notify health care provider for gait or coordination problems.
Oxcarbazepine (Trileptal)	Partial seizures	Monitor for hyponatremia.
Phenobarbital (Barbita, Luminal)	Generalized tonic-clonic seizures, partial seizures	Note that this is less desirable than other antiepileptic drugs (AEDs) because of sedation. Be aware that overdose can be fatal. Monitor for drowsiness, sleep disturbances, cognitive impairment, and depression.
Phenytoin (Dilantin), fosphenytoin (Cerebix)	All types, except absence, myoclonic, and atonic seizures; for status epilepticus	Monitor for gastric distress, gingival hyperplasia, anemia, ataxia, and nystagmus. Check CBC and calcium levels; monitor for therapeutic drug levels (10-20 mcg/mL) and toxic levels (>30 mcg/mL). For IV phenytoin, flush catheter with saline before and after administration. For fosphenytoin, use phenytoin equivalent for dosing.
Primidone (Mysoline, Sertan )	Partial seizures, generalized tonic-clonic seizures	Monitor for vertigo and lethargy. Watch for drug interactions with phenobarbital and isoniazid.
Tiagabine (Gabitril)	Partial seizures	Monitor for dizziness, weakness, nervousness, psychomotor slowing, nystagmus, and paresthesias. Administer with food.
Topiramate (Topamax)	Adjunctive therapy for intractable partial seizures	Monitor for ataxia, confusion, dizziness, and fatigue. Be aware of increased risk for renal calculi.
Valproate (Depakote), valproate sodium injection (Depacon)	Simple and complex absence seizures Adjunct therapy for partial complex and generalized tonic-clonic seizures	Monitor for hair loss, tremor, increased liver enzymes, bruising, and N/V. Monitor CBC, PT, PTT, AST.
Zonisamide (Zonegran)	Adjunctive therapy for partial seizures	Monitor CBC, platelets, and renal function. Assess mental status, especially memory.

AST, Aspartate aminotransferase; CBC, complete blood count; N/V, nausea and vomiting; PT, prothrombin time; PTT, partial thromboplastin time.

CHART 44-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Health Teaching for the Patient with Epilepsy

- Drug therapy information:
 - Name, dosage, time of administration
 - Actions to take if side effects occur
 - Importance of taking drug as prescribed and not missing a dose
 - What to do if a dose is missed or cannot be taken
 - Importance of having blood drawn for therapeutic or toxic levels as requested by the health care provider
- **Do not take any medication, including over-the-counter drugs, without asking your health care provider.**
- Wear a medical alert bracelet or necklace, or carry an ID card indicating epilepsy.
- Follow up with your neurologist, physician, or other health care provider as directed.
- Be sure a family member or significant other knows how to help you in the event of a seizure and knows when your health care provider or emergency medical services should be called.
- Investigate and follow state laws concerning driving and operating machinery.
- Avoid alcohol and excessive fatigue.
- Contact the Epilepsy Foundation (www.epilepsyfoundation.org) or other organized epilepsy group for additional information. Epilepsy Canada (www.epilepsy.ca) also provides resources and support.

recurrence of seizures or the life-threatening complication of status epilepticus (discussed below). Some patients may stop therapy because they do not have the money to purchase the drugs. Refer limited-income patients to the social services department for assistance or to a case manager to locate other resources.

A balanced diet, proper rest, and stress-reduction techniques usually minimize the risk for breakthrough seizures. Encourage the patient to keep a seizure diary to determine whether there are factors that tend to be associated with seizure activity. Patients should follow state law concerning allowances for driving a motor vehicle.

All states prohibit discrimination against people who have epilepsy. Patients who work in occupations in which a seizure might cause serious harm to themselves or others (e.g., construction workers, operators of dangerous equipment, pilots) may need other employment. They may need to decrease or modify strenuous or potentially dangerous physical activity to avoid harm, although this varies with each person. Various local, state, and federal agencies can help with finances, living arrangements, and vocational rehabilitation.

Seizure Precautions. Precautions are taken to prevent the patient from injury if a seizure occurs. Specific seizure precautions vary depending on health care agency policy.

! NURSING SAFETY PRIORITY

Action Alert

Seizure precautions include ensuring that oxygen and suctioning equipment with an airway are readily available. If the patient does not have an IV access, insert a saline lock, especially if he or she is at significant risk for generalized tonic-clonic seizures. The saline lock provides ready access if IV drug therapy must be given to stop the seizure.

CHART 44-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient During a Tonic-Clonic or Complete Partial Seizure

- Protect the patient from injury.
- Do not force anything into the patient's mouth.
- Turn the patient to the side to keep the airway clear.
- Loosen any restrictive clothing the patient is wearing.
- Maintain the patient's airway and suction as needed.
- Do not restrain or try to stop the patient's movement; guide movements if necessary.
- Record the time the seizure began and ended.
- At the completion of the seizure:
 - Take the patient's vital signs.
 - Perform neurologic checks.
 - Keep the patient on his or her side.
 - Allow the patient to rest.
 - Document the seizure (see [Chart 44-6](#)).

Siderails are rarely the source of significant injury, and the effectiveness of the use of padded siderails to maintain safety is debatable. Padded siderails may embarrass the patient and the family. Follow agency policy about the use of siderails because they may be classified as a restraint device. Other methods to protect the patient, such as placing a mattress on the floor, may be used instead of siderails.

Padded tongue blades do not belong at the bedside and should NEVER be inserted into the patient's mouth because the jaw may clench down as soon as the seizure begins! Forcing a tongue blade or airway into the mouth is more likely to chip the teeth and increase the risk for aspirating tooth fragments than prevent the patient from biting the tongue. Furthermore, improper placement of a padded tongue blade can obstruct the airway.

Seizure Management. The actions taken during a seizure should be appropriate for the type of seizure ([Chart 44-5](#)). For example, for a simple partial seizure, observe the patient and document the time that the seizure lasted. Redirect the patient's attention away from an activity that could cause injury. Turn the patient on the side during a generalized tonic-clonic or complex partial seizure because he or she may lose consciousness. If possible, turn the patient's head to the side to prevent aspiration and allow secretions to drain. Remove any objects that might injure the patient.

It is not unusual for the patient to become cyanotic during a generalized tonic-clonic seizure. The cyanosis is generally self-limiting, and no treatment is needed. Some health care providers prefer to give the high-risk patient (e.g., older adult, critically ill, or debilitated patient) oxygen by nasal cannula or facemask during the postictal phase. He or she is not restrained because this may cause injury and may worsen the situation, causing more seizure activity. For any type of seizure, carefully observe the seizure and document assessment findings ([Chart 44-6](#)).

Emergency Care: Acute Seizure and Status Epilepticus Management. Seizures occurring in greater intensity, number, or length than the patient's usual seizures are considered *acute*. They may also appear in clusters that are different from the patient's typical seizure pattern. Treatment with lorazepam (Ativan, Apo-Lorazepam) or diazepam

CHART 44-6 FOCUSED ASSESSMENT

Seizures: Nursing Observations and Documentation

- How often the seizures occur:
 - Date, time, and duration of the seizure
- Description of each seizure:
 - Tonic, clonic
 - Staring spells, blinking
 - Automatism
- Whether more than one type of seizure occurs
- Sequence of seizure progression:
 - Where the seizure began
 - Body part first involved
- Observations during the seizure:
 - Changes in pupil size and any eye deviation
 - Level of consciousness
 - Presence of apnea, cyanosis, and salivation
 - Incontinence of bowel or bladder during the seizure
 - Eye fluttering
 - Movement and progression of motor activity
 - Lip smacking or other automatism
 - Tongue or lip biting
- How long the seizures last
- When the last seizure took place
- Whether the seizures are preceded by an aura:
 - Dizziness, numbness, or visual disturbances
 - Gustatory (taste) or auditory disturbances
- What the patient does after the seizure:
 - Feels drowsy or weak
 - May resume normal behavior
 - May be unaware that the seizure took place
- How long it takes for the patient to return to pre-seizure status

(Valium, Meval 🍁, Vivol 🍁, Diastat [rectal diazepam gel]) may be given to stop the clusters to prevent the development of status epilepticus. IV phenytoin (Dilantin) or fosphenytoin (Cerebyx) may be added.

Status epilepticus is a medical emergency and is a prolonged seizure lasting longer than 5 minutes or repeated seizures over the course of 30 minutes. It is a potential complication of all types of seizures. *Seizures lasting longer than 10 minutes can cause death!* Common causes of status epilepticus include:

- Sudden withdrawal from antiepileptic drugs
- Infections
- Acute alcohol or drug withdrawal
- Head trauma
- Cerebral edema
- Metabolic disturbances

! NURSING SAFETY PRIORITY**Critical Rescue**

Convulsive status epilepticus must be treated promptly and aggressively! Establish an airway and notify the health care provider or Rapid Response Team immediately if this problem occurs! Establishing an airway is the priority for this patient's care. Intubation by an anesthesia provider or respiratory therapist (RT) may be necessary. Administer oxygen as indicated by the patient's condition. If not already in place, establish IV access with a large-bore catheter, and start 0.9% sodium chloride. The patient is usually placed in the intensive care unit for continuous monitoring and management.

Blood is drawn to determine arterial blood gas levels and to identify metabolic, toxic, and other causes of the uncontrolled seizure. Brain damage and death may occur in the patient with tonic-clonic status epilepticus. Left untreated, metabolic changes result, leading to hypoxia, hypotension, hypoglycemia, cardiac dysrhythmias, or lactic (metabolic) acidosis. Further harm to the patient occurs when muscle breaks down and myoglobin accumulates in the kidneys, which can lead to renal failure and electrolyte imbalance. *This is especially likely in the older adult.*

The drugs of choice for treating status epilepticus are IV push lorazepam (Ativan, Apo-Lorazepam 🍁) or diazepam (Valium). Diazepam rectal gel (Diastat) may be used instead. Lorazepam is usually given as 4 mg over a 2-minute period. This procedure may be repeated, if necessary, until a total of 8 mg is reached.

To prevent additional tonic-clonic seizures or cardiac arrest, a loading dose of IV phenytoin (Dilantin) is given and oral doses administered as a follow-up after the emergency is resolved. Initially, give phenytoin at no more than 50 mg/min using an infusion pump. An alternative to phenytoin is fosphenytoin (Cerebyx), a water-soluble phenytoin prodrug. It is compatible with most IV solutions. It also causes fewer cardiovascular complications than phenytoin and can be given in an IV dextrose solution. After administration, fosphenytoin converts to phenytoin in the body. Therefore the FDA requires the dosage to be written as a phenytoin equivalent (PE): 150 mg of fosphenytoin equals 100 mg of phenytoin. Give fosphenytoin at a rate of 100 to 150 mg/min IV piggyback.

Serum drug levels are checked every 6 to 12 hours after the loading dose and then 2 weeks after oral phenytoin has started. Teach the patient about the side and adverse effects of any AED that is prescribed (see Chart 44-3).

**NCLEX EXAMINATION CHALLENGE****Safe and Effective Care Environment**

A client with a history of seizures is placed on seizure precautions. What emergency equipment will the nurse provide at the bedside?

Select all that apply.

- A. Padded tongue blade
- B. Oxygen setup
- C. Nasogastric tube
- D. Suction setup
- E. Artificial oral airway

Surgical Management

Patients who cannot be managed effectively with drug therapy may be candidates for surgery, including vagal nerve stimulation (VNS) and conventional surgical procedures. VNS is a fairly new procedure that has been very successful for many patients with epilepsy.

Vagal Nerve Stimulation. Vagal nerve stimulation (VNS) may be performed for control of continuous simple or complex partial seizures. Patients with generalized seizures are not candidates for surgery because VNS may result in severe neurologic deficits. The stimulating device (much like a cardiac pacemaker) is surgically implanted in the left chest wall. An electrode lead is attached to the left vagus nerve, tunneled under the skin, and connected to a generator. The procedure usually takes 2 hours with the patient under

general anesthesia. The stimulator is activated by the physician either in the operating room or, more commonly, 2 weeks after surgery. Programming is adjusted gradually over a period of time. The pattern of stimulation is individualized to the patient's tolerance. The generator runs continuously, stimulating the vagus nerve according to the programmed schedule.

The patient can activate the VNS with a handheld magnet when experiencing an aura, thus aborting the seizure. Patients experience a change in voice quality, which signifies that the vagus nerve has been stimulated. They usually report a relief in intensity and duration of seizures and an improved quality of life.

Observe for complications after the procedure such as hoarseness (most common), cough, dyspnea, neck pain, or dysphagia (difficulty swallowing). Teach the patient to avoid MRIs, microwaves, shortwave radios, and ultrasound diathermy (a physical therapy heat treatment).

Conventional Surgical Procedures. A small percentage of patients with epilepsy cannot be fully controlled with drug therapy or VNS. When all other options are exhausted, conventional surgery may be needed to improve the patient's quality of life. The largest group of conventional surgical candidates includes those with complex partial seizures in the frontal or temporal lobe.

Before surgery, the patient is admitted to a special inpatient observation unit. While there, he or she has continuous electroencephalogram (EEG) recording, close observation, and in many hospitals, video monitoring at all times except during personal care activities. The patient is taken off all AEDs. After the seizure area is identified, electrodes may be surgically implanted into the brain tissue to identify the extent of the focal area. This step is followed by additional continuous EEG and video monitoring, as well as close observation by the nursing staff. The area is surgically removed if vital areas of brain function will not be affected.

Preoperative care is similar to that described for patients undergoing a craniotomy (see Chapter 47). Preoperative diagnostic tests include MRI and single-photon emission computed tomography (SPECT)/positron emission tomography (PET) scans as described in Chapter 43. An intracarotid amobarbital test (Wada test) and neuropsychological testing are also done. The Wada test assesses hemispheric lateralization of language and memory after injection of amobarbital, a short-acting anesthetic. This procedure establishes the safety of surgery to preserve language memory. Neuropsychological testing evaluates memory, visuospatial function, language function, and intelligence quotient (IQ) to identify deficiencies in the brain that might correspond to areas believed to be the epileptic region. It is also used to compare preoperative and postoperative cognitive functioning.

Another surgical approach, the *partial corpus callosotomy*, may be used to treat tonic-clonic or atonic seizures in patients who are not candidates for other surgical procedures. The surgeon sections the anterior two thirds of the corpus callosum, preventing neuronal discharges from passing between the two hemispheres of the brain. This surgery usually reduces the number and severity of the seizures, making them more likely to respond to more conventional drug therapy. This procedure is not as commonly done as other surgeries but is very successful for some patients.

INFECTIONS

MENINGITIS

Pathophysiology

Meningitis is an inflammation of the meninges that surround the brain and spinal cord. Bacterial and viral organisms are most often responsible for meningitis, although fungal meningitis and protozoal meningitis also occur. *Viral meningitis is usually self-limiting, and the patient has a complete recovery. Bacterial meningitis is potentially life threatening.* Regardless of the causative organism, symptoms are the same, but meningococcal meningitis causes the most severe presentation.

Usually, the patient has a predisposing condition such as otitis media, pneumonia, acute or chronic sinusitis, or sickle cell anemia that increases the likelihood of meningitis. A brain or spinal surgery may also contribute to the development of meningitis. Populations likely to have the disease include patients who are immunosuppressed or have infections elsewhere in the body and older adults, especially those with chronic debilitating diseases. In rare cases, tongue piercing has been associated with infections, including meningitis.

The organisms responsible for meningitis enter the central nervous system (CNS) via the bloodstream at the blood-brain barrier. Direct routes of entry occur as a result of penetrating trauma, surgical procedures, or a ruptured cerebral abscess. **Otorrhea** (ear discharge) or **rhinorrhea** (nasal discharge, or "runny nose"), which may be caused by a basilar skull fracture, may lead to meningitis as a result of the direct communication of cerebrospinal fluid (CSF) with the environment. The invading organisms travel throughout the CNS via the subarachnoid space. The organism produces an inflammatory response in the pia mater, the arachnoid, the CSF, and the ventricles. The **exudate** (pus) formed may spread to both cranial and spinal nerves, causing further neurologic deterioration. Increased intracranial pressure (ICP) may occur as a result of blockage of the flow of CSF, change in cerebral blood flow, or thrombus (blood clot) formation.

Viral meningitis, the most common type, is sometimes referred to as *aseptic meningitis*. It often results from a variety of viral illnesses, including measles, mumps, herpes simplex, and herpes zoster. The formation of exudate that is common in bacterial meningitis does not occur, and no organisms are obtained from the CSF. Inflammation occurs over the cerebral cortex, the white matter, and the meninges. The susceptibility of the brain tissue to the virus varies depending on which type of cell is involved. The herpes simplex virus alters cellular metabolism, which quickly results in necrosis of the cells. Other viruses cause an alteration in the production of enzymes or neurotransmitters, which results in cell dysfunction and possible neurologic defects.

Clinical manifestations of viral meningitis include fever, **photophobia** (light sensitivity), upper respiratory infection symptoms, headache, myalgias (muscle aches), nausea, and vomiting. Herpes simplex type 2 may cause genital lesions. A maculopapular rash is seen when the causative organism is an enterovirus. Treatment is symptomatic. If genital lesions are present, acyclovir may be prescribed.

Cryptococcus neoformans meningitis is the most common fungal infection that affects the central nervous system

(CNS) of patients with acquired immune deficiency syndrome (AIDS). Fulminant invasive fungal sinusitis is also a recognized cause of fungal meningitis. The clinical manifestations vary because the compromised immune system affects the inflammatory response. For example, some patients have fever and others do not. Almost all of them have headache, nausea, and vomiting and show a decline in mental status. Treatment is symptomatic and includes IV antifungal agents.

Meningococcal meningitis is a medical emergency with a fairly high mortality rate, often within 24 hours. Unlike other types, this disorder affects the meninges, the subarachnoid space, and brain tissue and is highly contagious. It occurs most often in fall and winter when upper respiratory tract infections commonly occur. The most frequently involved organisms responsible for bacterial meningococcal meningitis are *Streptococcus pneumoniae* (pneumococcal disease) and *Neisseria meningitidis*.

Meningococcal meningitis is the only type that occurs in outbreaks. It is most likely to occur in areas of high population density, such as college dormitories, military barracks, and crowded living areas. It also affects people with compromised immune systems and those with spleen damage or who have no spleen (Heavey, 2010).

The number of outbreaks on college campuses has been decreasing over the past few years because many states require students to be vaccinated against meningitis.

! NURSING SAFETY PRIORITY

Action Alert

Teach people who live in highly populated areas, group settings, or others at risk about the importance of getting several vaccines to prevent certain types of meningitis. In addition to two vaccines already available for meningococcal meningitis (Menactra and Menomune), the FDA-approved Menveo, a new vaccine which is effective for other infectious strains. The Centers for Disease Control and Prevention (CDC) recommends a single dose of either Meactra or Menveo for all children from ages 11 through 18 years and high-risk adults between 19 and 55 years of age. The most common adverse effects of Menveo are pain at the injection site, headache, and malaise (Heavey, 2010).

The number of cases of *Haemophilus influenzae* and pneumococcal meningitis has also decreased. Teach patients who are at risk for influenza (“flu”) and pneumonia to have vaccines as recommended by their health care provider. Encourage all older adults and those of any age with chronic illnesses to have these protective immunizations to prevent meningitis. Teach people to contact the Meningitis Foundation of America (www.meningitisfoundationofamerica.com) for more information.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Perform a complete neurologic and neurovascular assessment to detect clinical manifestations associated with a diagnosis of meningitis or suspected meningitis as outlined in Chart 44-7.

CHART 44-7 KEY FEATURES

Meningitis

- Decreased (or change in) level of consciousness
- Disoriented to person, place, and year
- Pupil reaction and eye movements:
 - Photophobia
 - Nystagmus
 - Abnormal eye movements
- Motor response:
 - Normal early in disease process
 - Hemiparesis, hemiplegia, and decreased muscle tone possible later
 - Cranial nerve dysfunction, especially CN III, IV, VI, VII, VIII
- Memory changes:
 - Attention span (usually short)
 - Personality and behavior changes
 - Bewilderment
- Severe, unrelenting headaches
- Generalized muscle aches and pain
- Nausea and vomiting
- Fever and chills
- Tachycardia
- Red macular rash (meningococcal meningitis)

Physical Assessment/Clinical Manifestations

Signs and symptoms of meningitis result from meningeal irritation. Assess for fever, headache, and altered mental status. The patient may also report photophobia and have signs of increased intracranial pressure (ICP), such as decreasing level of consciousness. Although the classic **nuchal rigidity** (stiff neck) and positive Kernig’s and Brudzinski’s signs have been traditionally used to diagnose meningitis, these findings occur in only a small percentage of patients with a definitive diagnosis. Seizures may also occur, particularly in bacterial meningitis. Older adults, patients who are immunocompromised, and those who have been inadequately treated with antibiotics may not have fever.

Assess the patient for complications, including increased ICP resulting from the presence of exudate (pus), which can lead to hydrocephalus and cerebral edema. Left untreated, increased ICP can lead to herniation of the brain and death (see Chapter 47).

Seizure activity may be caused by irritation of the cerebral cortex. Because of abnormal stimulation of the hypothalamic area, excessive amounts of antidiuretic hormone (ADH) (vasopressin) are produced. This results in water retention and dilution of serum sodium caused by increased sodium loss by the kidneys. This syndrome of inappropriate antidiuretic hormone (SIADH) production may lead to further increases in ICP.

Assess the patient’s vascular status by:

- Observing the color and temperature of the extremities
- Determining the presence of peripheral pulses
- Identifying any indicators of abnormal bleeding

Septic emboli in the blood may block circulation in the small vessels of the hands and feet, leading to gangrene. Excessive fibrinolysis (breakdown of fibrin clots) that occurs in bacteremia and infections from viruses, fungi, or protozoa may lead to disseminated intravascular coagulation (DIC). Involvement of the cerebral arteries, veins, and venous sinuses may lead to seizures and hemiparesis.

TABLE 44-2 CEREBROSPINAL FLUID FINDINGS IN BACTERIAL AND VIRAL MENINGITIS

FINDING	BACTERIAL MENINGITIS	VIRAL MENINGITIS
Appearance	Cloudy, turbid	Clear
White blood cells	Increased	Increased
Protein	Increased	Slightly increased
Glucose	Decreased	Most often normal, but may be decreased
CSF pressure	Elevated	Varies

Laboratory Assessment

The most significant laboratory test used in the diagnosis of meningitis is the analysis of the *cerebrospinal fluid (CSF)*. Patients older than 60 years, those who are immunocompromised, or those who have signs of increased ICP usually have a CT scan before the lumbar puncture. If there will be a delay in obtaining the CSF, blood is drawn for culture and sensitivity. A broad-spectrum antibiotic should be given before the lumbar puncture. The CSF is analyzed for cell count, differential count, and protein. Glucose concentrations are determined, and culture, sensitivity, and Gram stain studies are performed (Table 44-2).

Counterimmunoelectrophoresis (CIE) may be performed to determine the presence of viruses or protozoa in the CSF. CIE is also indicated if the patient has received antibiotics before the CSF was obtained. To identify a possible bacterial source of infection, specimens for culture are obtained and Gram stains of the urine, throat, and nose are also performed. Table 44-2 compares CSF findings in bacterial meningitis and viral meningitis.

A complete blood count (CBC) is performed. The white blood cell (WBC) count is usually elevated well above the normal value. Serum electrolyte values are also assessed. Dilutional hyponatremia may occur as a result of SIADH, a complication of bacterial meningitis.

Other Diagnostic Assessment

X-rays of the chest, air sinuses, and mastoids are obtained to determine the presence of infection. A CT or MRI scan may be performed to identify increased ICP, the presence of a brain abscess, or developing hydrocephalus.

INTERVENTIONS

The most important nursing interventions for patients with meningitis are accurately monitoring and documenting their neurologic status. Best practices for nursing care are listed in Chart 44-8.

! NURSING SAFETY PRIORITY

Action Alert

For the patient with meningitis, assess his or her neurologic status and vital signs at least every 4 hours or more often if clinically indicated. *The priority for care is to monitor for early neurologic changes that may indicate increased ICP, such as decreased level of consciousness (LOC).* The patient is also at risk for seizure activity. Care should be provided as discussed in Interventions on p. 933 in the Seizures and Epilepsy section.

CHART 44-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with Meningitis

- Follow ABCs (a_{ir}way, b_{re}athing, c_{irc}ulation).
- Take vital signs and perform neurologic checks every 2 to 4 hours, as required.
- Perform cranial nerve assessment, with particular attention to cranial nerves III, IV, VI, VII, and VIII, and monitor for changes.
- Manage pain with drug and nondrug methods.
- Perform vascular assessment, and monitor for changes.
- Give drugs and IV fluids as prescribed, and document the patient's response.
- Record intake and output carefully to maintain fluid balance and prevent fluid overload.
- Monitor body weight to identify fluid retention early.
- Monitor laboratory values closely; report abnormal findings to the physician or nurse practitioner promptly.
- Position carefully to prevent pressure ulcers.
- Perform range-of-motion exercises every 4 hours as needed.
- Decrease environmental stimuli:
 - Provide a quiet environment.
 - Minimize exposure to bright lights from windows and overhead lights.
 - Maintain bedrest with head of bed elevated 30 degrees.
- Maintain Transmission-Based Precautions per hospital policy (for bacterial meningitis).
- Monitor for and prevent complications:
 - Increased intracranial pressure
 - Vascular dysfunction
 - Fluid and electrolyte imbalance
 - Seizures
 - Shock

Cranial nerve testing is included as part of the routine neurologic assessment because of possible cranial nerve involvement. Particular attention is given to cranial nerves III, IV, VI, VII, and VIII (see Chapter 43). A *sixth cranial nerve defect (inability to move the eyes laterally)* may indicate the development of **hydrocephalus** (excessive accumulation of CSF within the brain's ventricles). Other indicators of hydrocephalus include signs of increased ICP and urinary incontinence. Urinary incontinence results from decreasing LOC.

To avoid life-threatening complications, the health care provider prescribes a broad-spectrum antibiotic until the results of the culture and Gram stain are available. After this information is available, the appropriate anti-infective drug to treat the specific type of meningitis is given. Treatment of bacterial meningitis generally requires a 2-week course of IV antibiotics. Drug therapy should begin within 1 to 2 hours after it is prescribed. Monitor and document the patient's response.

The patient with bacterial meningitis may experience increased ICP, and seizure activity may occur. Drugs used by the physician to treat these complications include hyperosmolar agents and antiepileptic drugs (AEDs). Controversy exists as to whether steroids are helpful in the treatment of all adults with meningitis. They are, however, recommended for patients with *S. pneumoniae* meningitis. People who have been in close contact with a patient with *N. meningitidis* should have prophylaxis (preventive) treatment with rifampin (Rifadin, Rofact ) or ciprofloxacin (Cipro), or ceftriaxone (Rocephin). Preventive treatment with rifampin may be prescribed for those in close contact with a patient with *H. influenzae* meningitis.

Perform a complete vascular assessment every 4 hours or more often, if indicated, to detect early vascular compromise from septic emboli. This severe complication is most often seen in circulation to the hand. Assess the patient's temperature, color, pulses, and capillary refill in the fingernails. If vascular compromise is not noticed and left untreated, gangrene can develop quickly, possibly leading to loss of the involved arm. The health care team monitors the patient for other complications, including septic shock, coagulation disorders, acute respiratory distress syndrome, and septic arthritis. These health problems are discussed elsewhere in this textbook.

Standard Precautions are appropriate for all patients with meningitis unless the patient has a bacterial type that is transmitted by droplets, such as *N. meningitidis* and *H. influenzae*.

! NURSING SAFETY PRIORITY

Action Alert

Place the patient with bacterial meningitis that is transmitted by droplets on Droplet Precautions *in addition to* Standard Precautions. When possible, place the patient in a private room. Stay at least 3 feet from the patient unless wearing a mask. Patients who are transported outside of the room should wear a mask and follow respiratory hygiene/cough etiquette (see Chapter 25). Teach visitors about the need for these precautions and how to follow them.

ENCEPHALITIS

Pathophysiology

Encephalitis is an inflammation of the brain tissue and often the surrounding meninges. It affects the cerebrum, the brainstem, and the cerebellum. A viral agent most often causes the disease, although bacteria, fungi, or parasites may also be involved (e.g., malaria). The virus travels to the central nervous system (CNS) via the bloodstream, along peripheral or cranial nerves, or in the meninges (e.g., varicella zoster). Therefore viral encephalitis can be life threatening or lead to persistent neurologic problems such as learning disabilities, epilepsy, memory deficits, or fine motor deficits.

After the virus invades the brain tissue, it begins to reproduce, causing an inflammatory response. Unlike in meningitis, this response does not cause exudate (pus) formation. Inflammation extends over the cerebral cortex, the white matter, and the meninges, causing degeneration of the neurons of the cortex. Demyelination of axons occurs in the involved area because the white matter is destroyed. This leads to hemorrhage, edema, necrosis (cell death), and the development of small lacunae (hollow cavities) within the cerebral hemispheres. Widespread edema can cause compression of blood vessels leading to a further increase in intracranial pressure (ICP). Death may occur from herniation and increased ICP.

Arboviruses can be transmitted to humans through the bite of an infected mosquito or tick. The most common types of encephalitis caused by arboviruses are Eastern or Western equine encephalitis, St. Louis encephalitis, California encephalitis, and West Nile virus.

West Nile virus has gained attention in the United States because it has spread rapidly throughout the country and is a potentially serious illness. This infection is typically mild,

and usually the patient is asymptomatic. However, a small percentage of patients develop severe disease. The incubation period is 2 to 15 days after being bitten by an infected mosquito. Other possible sources of transmission include blood products, breast milk, or an organ transplant. Diagnostic tests to determine the presence of West Nile virus include enzyme-linked immunosorbent assay and West Nile virus-specific IgM antibody in the blood or CSF.

In mild cases, the patient has no symptoms or has mild flu-like symptoms (e.g., fever, body aches, nausea, vomiting). Some people develop serious symptoms that may include high fever, severe headache, decreased level of consciousness, tremors, vision loss, seizures, and muscle weakness or paralysis. These manifestations may last for several weeks, and neurologic deficits may be permanent. A few patients die from the disease.

Echovirus, coxsackievirus, poliovirus, herpes zoster, and viruses that cause mumps and chickenpox are the common *enteroviruses* associated with encephalitis. *Herpes simplex virus type 1* (HSV1) encephalitis is the most common non-epidemic type of encephalitis in North America. Patients with this disease often have a history of cold sores. The mortality rates for HSV1 encephalitis are very high compared with those for other types of encephalitis.

Amebic meningoencephalitis is caused by the amebae *Naegleria* and *Acanthamoeba*. Both are found in warm freshwater areas and can enter the nasal mucosa of people swimming in ponds or lakes. The *amebae* may also be found in soil and decaying vegetation. Although this infection has not often been seen in the past, the incidence in North America is increasing, perhaps because ponds and lakes are becoming more polluted.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The typical patient with encephalitis has a fever and reports nausea, vomiting, and a stiff neck. Assess for other clinical manifestations, including:

- High fever
- Changes in mental status (e.g., agitation)
- Motor dysfunction (e.g., dysphagia [difficulty swallowing])
- Focal (specific) neurologic deficits
- Photophobia (light sensitivity) and phonophobia (noise sensitivity)
- Fatigue
- Symptoms of increased ICP (e.g., decreased LOC)
- Joint pain
- Headache

Assess LOC using the Glasgow Coma Scale (see Chapter 43) or other agency-approved assessment tool. The patient may be lethargic, stuporous, or comatose. Mental status changes are more extensive in the patient with encephalitis than with meningitis. Changes include acute confusion, irritability, and personality and behavior changes (especially noted in the presence of herpes simplex). Signs of meningeal irritation include the presence of nuchal (neck) rigidity and motor changes that vary from a mild weakness to hemiplegia. The patient may have muscle tremors, spasticity, an ataxic gait

(postencephalitic parkinsonism), myoclonic jerks, and increased deep tendon reflexes. Seizure activity is common. Nausea, vomiting, headache, and vertigo also may occur.

Observe for cranial nerve involvement, such as ocular palsies (paralysis), facial weakness, and nystagmus (involuntary lateral eye movements). The herpes zoster lesion affects cranial and spinal nerve root ganglia, which is clinically manifested by a rash, severe pain, itching, burning, or tingling in the areas innervated by these nerves.

! NURSING SAFETY PRIORITY

Critical Rescue

In severe cases of encephalitis, the patient may have increased ICP resulting from cerebral edema, hemorrhage, and necrosis of brain tissue. Monitor vital signs for indications of a widened pulse pressure, bradycardia, and irregular respirations. The pupils become increasingly dilated and less responsive to light. Left untreated, increased ICP leads to herniation of the brain tissue and possibly death (see Chapter 47).

Lumbar puncture (LP) is done to analyze the CSF for the specific offending organism. A polymerase chain reaction (PCR) test may be used to detect viral DNA or ribonucleic acid (RNA) in the CSF. Specificity and sensitivity in diagnosing encephalitis are excellent, especially with herpes simplex virus (HSV). The test is rapid and noninvasive, replacing the brain biopsy for diagnosis.

An electroencephalogram is done to evaluate brain wave activity to detect seizures. Brain imaging in the form of a CT scan with and without contrast is performed to evaluate elevated intracranial pressure (ICP) or obstructive hydrocephalus.

INTERVENTIONS

Teach people who live in mosquito-infested areas to protect themselves and their families from West Nile virus infections. Chart 44-9 lists measures for preventing this infection. There is no curative treatment for West Nile viral encephalitis.

Acyclovir (Zovirax) is the antiviral drug of choice for the treatment of herpes encephalitis and is associated with a significantly lower mortality rate than vidarabine (Vira-A). Drug therapy is most effective if begun early, before the patient becomes stuporous or comatose. This neurologic decline usually occurs within 4 to 6 days after the initial neurologic symptoms. No specific drug therapy is available for infection by arboviruses or enteroviruses.

CHART 44-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Protecting the Patient and Family from West Nile Virus

- Limit your time outside between dusk and dawn when mosquitoes are out.
- Wear protective clothing, including long sleeves and pants.
- Use an insect repellent containing DEET when outdoors.
- Remove areas of standing water from flower pots, trash cans, and rain gutters.
- Check window and door screens for holes that need repair.
- Keep hot tubs and pools clean and properly chlorinated.

Nursing interventions for encephalitis are similar to those for meningitis with the exception of drug therapy. Supportive nursing care and prompt recognition and treatment of increased ICP are essential components of management. *Maintain a patent airway to prevent the development of atelectasis or pneumonia, which can lead to further brain hypoxia (lack of oxygen).*

Provide supportive nursing care for the patient who is immobile, stuporous, or comatose. Delegate and supervise unlicensed assistive personnel (UAP) to turn, cough, and deep breathe the patient at least every 2 hours. Perform deep tracheal suctioning even in the presence of increased ICP if respiratory status is compromised. Assess vital signs and neurologic signs every 2 hours or more frequently if clinically indicated. Elevate the head of the bed 30 to 45 degrees unless contraindicated (e.g., after lumbar puncture or in the patient with severe hypotension). Keep the patient's room darkened and quiet to promote comfort and decrease agitation. Remind UAP to provide safety measures such as keeping the bed in the lowest position.

Provide patient and family support. Families need health teaching to understand how to care for their loved ones. They are often fearful that the patient may not return to his or her baseline. Collaborate with a certified chaplain, social worker, or case manager to provide additional emotional support and counseling.

Patients with encephalitis and permanent neurologic deficits are usually discharged to a rehabilitation setting or a long-term care facility. Those with minimal neurologic problems are discharged to the home setting.

PARKINSON DISEASE

Pathophysiology

Parkinson disease (PD), also referred to as *Parkinson's disease* and *paralysis agitans*, is a progressive neurodegenerative disease that is the one of the most common neurologic disorders of older adults. It is a debilitating disease affecting motor ability and is characterized by four cardinal symptoms: tremor, rigidity, **bradykinesia** or **akinesia** (slow movement/no movement), and postural instability. Most people have *primary*, or idiopathic, disease. A few patients have *secondary* parkinsonian symptoms from conditions such as brain tumors and certain anti-psychotic drugs.

Motor activity occurs as a result of integrating the actions of the cerebral cortex, basal ganglia, and cerebellum. The basal ganglia are a group of neurons located deep within the cerebrum at the base of the brain near the lateral ventricles. When the basal ganglia are stimulated, muscle tone in the body is inhibited and voluntary movements are refined. The secretion of two major neurotransmitters accomplishes this process: dopamine and acetylcholine (ACh).

Dopamine is produced in the substantia nigra, as well as in the adrenal glands, and is transmitted to the basal ganglia along a connecting neural pathway for secretion when needed. ACh is produced and secreted by the basal ganglia, as well as in the nerve endings in the periphery of the body. ACh-producing neurons transmit *excitatory* messages throughout the basal ganglia. Dopamine *inhibits* the function of these neurons, allowing control over voluntary movement. This system of checks and balances allows for refined, coordinated movement, such as picking up a pencil and writing.

TABLE 44-3 STAGES OF PARKINSON DISEASE

Stage 1: Initial Stage • Unilateral limb involvement • Minimal weakness • Hand and arm trembling	Stage 3: Moderate Disease • Postural instability • Increased gait disturbances
Stage 2: Mild Stage • Bilateral limb involvement • Masklike facies • Slow, shuffling gait	Stage 4: Severe Disability • Akinesia • Rigidity
	Stage 5: Complete ADL Dependence

Widespread degeneration of the *substantia nigra* then leads to a decrease in the amount of dopamine in the brain. When dopamine levels are decreased, a person loses the ability to refine voluntary movement. The large number of excitatory ACh-secreting neurons remain active, creating an imbalance between excitatory and inhibitory neuronal activity. The resulting excessive excitation of neurons prevents a person from controlling or initiating voluntary movement.

Not only does PD interfere with movement as a result of dopamine loss in the brain, it also reduces the sympathetic nervous system influence on the heart and blood vessels. This loss results in the orthostatic hypotension frequently seen in the patient with PD.

PD is separated into stages according to the symptoms and degree of disability. Stage 1 is mild disease with unilateral limb involvement, whereas the patient with stage 5 disease is completely dependent in all ADLs. Other classifications refer simply to mild, moderate, and severe disease (Table 44-3).

Although the exact cause of PD is not known, it is probably due to environmental and genetic factors. Exposure to pesticides, herbicides, and industrial chemicals and metals and drinking well water, being older than 40 years, and having reduced estrogen levels are known risk factors for the development of PD.

GENETIC/GENOMIC CONSIDERATIONS

Primary Parkinson disease (PD) often has a familial tendency. The disease is associated with deletion of mitochondrial DNA (mtDNA). These deletions cause a loss of neurons that produce dopamine in the substantia nigra (Nussbaum et al., 2007). Specific genetic mutations have been identified in some families with PD. Of the genetic mutations identified, the *parkin 1* gene on chromosome 4 has been the most studied. In the presence of a genetic mutation, alpha-synuclein, a major component of Lewy bodies, is produced and thought to contribute to neuronal death (McCance et al., 2010).

As the population ages, the number of people affected by PD is expected to dramatically increase. Approximately 50% more men than women currently have the disease.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Collect data related to the time and progression of symptoms noticed by the patient or the family. The older adult, who may assume that these behaviors are normal changes associated

CHART 44-10 KEY FEATURES

Parkinson Disease

- Posture:
 - Stooped posture
 - Flexed trunk
 - Fingers abducted and flexed at the metacarpophalangeal joint
 - Wrist slightly dorsiflexed
- Gait:
 - Slow and shuffling
 - Short, hesitant steps
 - Propulsive gait
 - Difficulty stopping quickly
- Motor:
 - **Bradykinesia** (slow movement)
 - Muscular rigidity
 - Akinesia
 - Tremors
 - “Pill-rolling” movement
 - Masklike facies
 - Difficulty chewing and swallowing
 - Uncontrolled drooling, especially at night
 - Fatigue
 - Difficulty getting into and out of bed
 - Reduced arm swinging on one side of the body when walking
 - Micrographia (change in handwriting or handwriting gets smaller)
- Speech:
 - Soft, low-pitched voice
 - **Dysarthria** (slurred speech)
 - **Echolalia** (automatic repetition of what another person says) and repetition of sentences
 - **Hypophonia** (soft voice), change in voice volume or articulation
- Autonomic dysfunction:
 - Orthostatic hypotension
 - Excessive perspiration
 - Oily skin
 - Seborrhea
 - Flushing
 - Changes in skin texture
 - Blepharospasm (eyelid spasm)
- Psychosocial assessment:
 - Emotionally labile
 - Depressed
 - Paranoid
 - Easily upset
 - Rapid mood swings
 - Cognitive impairments (i.e., dementia)
 - Delayed reaction time
 - Sleep disturbances

with aging, may ignore early signs and symptoms such as *resting* tremors, bradykinesia (slowed movement), and problems with muscular rigidity. Tremors are usually noticed in the upper extremities first and may increase with stress. Slow voluntary movements and reduced automatic movements may be manifested by a change in the patient’s handwriting. Some patients report “freezing” because they feel that they are stuck to the floor. Chart 44-10 summarizes the clinical manifestations of Parkinson disease. Assess the patient for **rigidity**, or resistance to passive movement of the extremities, which is classified as:

- *Cogwheel*, manifested by a rhythmic interruption of the muscle movement
- *Plastic*, defined as mildly restrictive movement
- *Lead pipe*, or total resistance to movement

FIG. 44-1 The masklike facial expression typical of patients with Parkinson disease.

Rigidity is present early in the disease process and progresses over time. Observe the patient's ability to relax a muscle or move a selected muscle group.

Changes in facial expression or a **masklike facies** with wide-open, fixed, staring eyes is caused by rigidity of the facial muscles (Fig. 44-1). This rigidity can lead to difficulties in chewing and swallowing, particularly if the pharyngeal muscles are involved. As a result, the patient may have inadequate nutrition. Uncontrolled drooling may occur. Some patients develop dementia later as the disease progresses. In addition to changes in voluntary movement, many patients experience autonomic nervous system symptoms, such as excessive perspiration and orthostatic hypotension. Orthostatic hypotension was originally thought to be a side effect of levodopa therapy. However, it is probably related to loss of sympathetic innervation in the heart and blood vessel response.

Patients can also develop emotional changes such as depression, irritability, pessimism, fear, and insecurity. These symptoms may develop because patients fear that they will not be able to cope with new situations.

Changes in speech pattern are common in PD patients. They may speak very softly, slur or repeat their words, use a monotone voice or a halting speech, hesitate before speaking, or exhibit a rapid speech pattern.

Bowel and bladder problems are commonly seen in PD due to malfunction of the autonomic nervous system, which regulates smooth muscle activity. Patients can exhibit symptoms of either urinary incontinence or difficulty urinating. Constipation can occur due to the slow motility of the GI tract or because of poor dietary habits and poor fluid intake.

The diagnosis of PD is made based on clinical findings after other neurologic diseases are eliminated as possibilities. There are no specific diagnostic tests. Analysis of cerebrospinal fluid (CSF) may show a decrease in dopamine levels, although the results of other studies are usually normal. Other diagnostic tests may be done such as an MRI, single-

CHART 44-11 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient with Parkinson Disease

- Allow the patient extra time to respond to questions.
- Administer medications promptly on schedule to maintain continuous therapeutic drug levels.
- Provide medication for pain, tingling in limbs, as needed.
- Monitor for side effects of medications, especially orthostatic hypotension, hallucinations, and acute confusional state (delirium).
- Collaborate with physical and occupational therapists to keep the patient as mobile and as independent as possible in ADLs.
- Allow the patient time to perform ADLs and mobility skills.
- Implement interventions to prevent complications of immobility, such as constipation, pressure ulcers, and contractures.
- Schedule appointments and activities late in the morning to prevent rushing the patient, or schedule them at the time of the patient's optimal level of functioning.
- Teach the patient to speak slowly and clearly. Use alternative communication methods, such as a communication board. Refer to speech-language pathologist.
- Monitor the patient's ability to eat and swallow. Monitor actual food and fluid intake. Collaborate with the dietitian.
- Provide high-protein, high-calorie foods or supplements to maintain weight.
- Recognize that Parkinson disease affects the patient's body image. Focus on the patient's strengths.
- Assess for depression and anxiety.
- Assess for insomnia or sleeplessness.

photon emission computed tomography (SPECT), or a positron emission tomography (PET).

INTERVENTIONS

In addition to the health care provider, physical and/or occupational therapist, speech-language pathologist, dietitian, and case manager, collaborate with the patient and family to develop a collaborative plan of care. In some cases, palliative surgery may be performed to assist the patient to remain mobile for as long as possible. Chart 44-11 summarizes best practices for nursing management of the patient with PD.

Nonsurgical Management

Drug therapy is an essential part of management, which decreases signs and symptoms and allows the patient to provide self-care and have a reasonable quality of life. One of the most important desired outcomes is that the patient will improve *mobility (movement)*, a basic human need.

Drug Therapy. Drugs are prescribed to treat the symptoms of PD with the purpose of increasing the patient's functional abilities and quality of life. An equally important desired outcome is to prescribe drugs with minimal long-term side effects. Many questions and controversies remain about which drugs to use, when to start therapy, and how to prevent complications. Drug administration is closely monitored, and the health care provider adjusts the dosage or changes therapy as the patient's condition requires. Teach the patient and family how to monitor for and report adverse effects of drug therapy.

Dopamine agonists mimic dopamine by stimulating dopamine receptors in the brain. They are typically the most effective during the first 3 to 5 years of use. The benefit of these agents is fewer incidents of **dyskinesias** (problems with

movement) and “**wearing off**” **phenomenon** (loss of response to the drug) when compared with other drugs. This problem is characterized by periods of good mobility (“on”) alternating with periods of poor mobility (“off”). Patients report that their most distressing symptom is “off time.”

Examples of dopamine agonists are apomorphine (Apokyn [a morphine derivative]), pramipexole (Mirapex), and ropinirole (Requip). Another drug in this class, rotigotine, is available as a continuous transdermal patch (Neupro) to maintain a consistent level of dopamine.

! NURSING SAFETY PRIORITY

Drug Alert

Dopamine agonists are associated with adverse effects such as orthostatic (postural) hypotension, hallucinations, sleepiness, and drowsiness. Remind patients to avoid operating heavy machinery or driving if they have any of these symptoms. Teach them to change from a lying or sitting position to standing by moving slowly. The health care provider should not prescribe drugs in this class to older adults because of their severe adverse drug effects.

Almost all patients are on Sinemet, a combination *levodopa-carbidopa* drug, at some point in their disease. It may be the initial drug of choice if the patient’s presenting symptoms are severe or interfere with work or school. Both an immediate-release (IR) and controlled-release (CR) form of Sinemet in varying doses are available. The levodopa agents are less expensive than the dopamine agonists and are better at improving motor function. Long-term use leads to dyskinesia (inability to perform voluntary movement). Teach the patient and family to give the drug before meals to increase absorption and transport across the blood-brain barrier.

Catechol O-methyltransferases (COMTs) are enzymes that inactivate dopamine. Therefore COMT *inhibitors* block this activity, thus prolonging the action of levodopa. One example is entacapone (Comtan), which is often used in combination with levodopa. Stalevo is a combination of levodopa, carbidopa, and entacapone. The benefit of these combinations is that the disease is treated in several ways with one drug. However, they are not beneficial for those patients who need more specific dosages of individual drugs.

Monamine oxidase type B (MAO-B) inhibitors (MAOIs) are more popular for use in patients with early or mild symptoms of PD. Entacapone (Comtan) and selegiline (Deprenyl, Eldepryl) are often given with levodopa for early or mild disease. A newer MAOI-B for PD is rasagiline mesylate (Azilect), which can be given as a single drug or with levodopa. This drug has been reported to decrease “freezing” episodes (Cranwell-Bruce, 2010).

The MAOI-B drugs work by slowing the main type (B) of monamine oxidase in the brain, increasing dopamine concentrations and helping reduce the clinical manifestations of

PD. They may also protect neurons in the brain (Cranwell-Bruce, 2010).

When other drugs are no longer effective, bromocriptine mesylate (Parlodel), a *dopamine receptor antagonist*, may be prescribed to promote the release of dopamine. It may be used alone or in combination with carbidopa/levodopa (Sinemet). Some providers may prescribe Parlodel early in the course of treatment. It is especially useful in the patient who has experienced side effects such as dyskinesias or orthostatic hypotension while receiving Sinemet.

Amantadine (Symmetrel) is an *antiviral drug* that has anti-Parkinson benefits. It may be given early in disease to reduce symptoms. It is also prescribed with Sinemet to reduce dyskinesias. Rivastigmine (Exelon) is a *cholinesterase inhibitor* that is used only when patients with PD have dementia. This drug works to improve the transmission of acetylcholine in the brain by delaying its destruction by the enzyme *acetylcholinesterase*.

For severe motor symptoms such as tremors and rigidity, one of the older *anticholinergic* drugs may be prescribed, but they are rarely used as primary drugs of choice for Parkinson disease (PD) (Cranwell-Bruce, 2010). Examples are benztropine (Cogentin), trihexyphenidyl HCl (Artane), and procyclidine (Kemadrin). *These drugs should be avoided in older adults because they can cause acute confusion, urinary retention, constipation, dry mouth, and blurred vision. Newer and safer drugs are now available for this age-group.*

For the patient on any long-term drug therapy regimen, drug tolerance or *drug toxicity* often develops. Drug toxicity may be evidenced by delirium (acute confusion), cognitive impairment, decreased effectiveness of the drug, or hallucinations. Delirium may be difficult to assess in the patient who is already suffering from chronic dementia as a result of PD or another disease. If possible, compare the patient’s current cognitive and behavioral status with his or her baseline before drug therapy began.

When drug tolerance is reached, the drug’s effects do not last as long as previously. The treatment of PD drug toxicity or tolerance includes:

- A reduction in drug dosage
- A change of drug or in the frequency of administration
- A drug holiday (particularly with levodopa therapy)

During a **drug holiday**, which typically lasts up to 10 days, the patient receives no drug therapy for PD. Carefully monitor the patient for symptoms of PD during this time, and document assessment findings.

Many patients are on additional drugs to help relieve symptoms associated with the disease. For example, muscle spasms may be relieved by baclofen (Kemstro), drooling can be minimized by sublingual atropine sulfate (Atropair), and insomnia may require a sleeping aid like zolpidem tartrate (Ambien). If patients also become moderately to severely depressed, an antidepressant such as short-acting venlafaxine (Effexor) may be prescribed. This complicated drug regimen may be confusing to patients. A study by Fincher et al. (2009) demonstrated that telehealth technology was very beneficial in helping to educate patients and maintain drug adherence. Videophone users were more satisfied with the equipment and counseling than telephone sessions (see the **Evidence-Based Practice** box on p. 945).

Other Interventions. A *freezing gait and postural instability* are major problems for patients with PD. Nontraditional

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients taking MAOIs about the need to avoid foods, beverages, and drugs that contain tyramine, including cheese and aged, smoked, or cured foods and sausage. Remind them to also avoid red wine and beer to prevent severe headache and life-threatening hypertension (Lilley et al., 2011). Patients should continue these restrictions for 14 days after the drug is discontinued.

EVIDENCE-BASED PRACTICE

Does Telehealth Technology Improve Learning for Patients with Parkinson's Disease Who are Taking Multiple Medications?

Fincher, L., Ward, C., Dawkins, V., Magee, V., & Willson, P. (2009). Using telehealth to educate Parkinson's disease patients about complicated medication regimens. *Journal of Gerontological Nursing*, 35(2), 16-24.

Parkinson disease (PD) affects primarily older adults who often have complex drug regimens to manage their symptoms. Patients (veterans) taking three or more medications for PD were randomly assigned to three groups of 25 each to receive nurse-conducted patient education about their drug regimen using one of three modalities: video phone, telephone, or face-to-face. The patients ranged in age from 50 to 84 years, and most were Caucasian men. After the initial educational session using one of the three modalities, patients were followed at 3-month intervals for 6 months using either the telephone or videophone. Patient satisfaction was measured by a 15-item rating scale after the 6 months was completed. Satisfaction was the highest in the group who used the videophone when compared with the telephone users. All of the study participants thought that telehealth modalities are a convenient method for learning or reinforcing knowledge.

Level of Evidence: 3

The researchers used random assignment to compare the effect of multiple modalities for patient education and reinforcement.

Commentary: Implications for Practice and Research

Health technology is increasing and assisting in patient education, monitoring, and adherence to the collaborative plan of care. Nurses can be instrumental in starting or conducting telehealth programs, especially for patients with chronic illnesses who are at risk for complications for adverse drug events. More studies are needed to investigate the use of telehealth so that patients can stay at home and reduce repeated admissions to the hospital. These studies should have a larger sample and consist of a more diverse population. Telehealth technology is a major asset to ensure continuity of care.

exercise programs, such as yoga and tai chi, may help elevate mood, as well as improve mobility, in the early stage of the disease. Early in the disease process, collaborate with physical and occupational therapists to plan and implement a program to keep the patient mobile and flexible by incorporating active and passive range-of-motion (ROM) exercises, muscle stretching, and activity. Remind the patient to avoid concentrating on his or her feet when walking to prevent falls.

In collaboration with the rehabilitation team, encourage the patient to participate as much as possible in self-management, including ADLs. The team makes the environment conducive to independence in activity and as stress-free and safe as possible. Occupational and physical therapists provide training in ADLs and the use of adaptive devices, as needed, to facilitate independence. The occupational therapist (OT) evaluates the patient for the need for adaptive devices (e.g., special utensils for eating).

Patients with PD tend to not sleep well at night because of drug therapy and the disease itself. Some patients nap for short periods during the day and may not be aware that they have done so. This sleep misperception may put the patient at risk for injury. For example, he or she may fall asleep while driving an automobile. Therefore teach the patient and family to monitor the patient's sleeping pattern and discuss whether he or she can operate machinery or perform other potentially high-risk tasks safely.

Collaborate with the dietitian, if needed, to evaluate the patient's food intake and ability to eat. The patient's intake of calcium, vitamin K, and other nutrients is evaluated, especially in the patient who is susceptible to falling or has difficulty swallowing. The dietitian considers the patient's bowel habits and adjusts the diet if constipation occurs. If the patient has trouble swallowing, collaborate with the speech-language pathologist (SLP) for an extensive swallowing evaluation. Based on these findings and the patient interview, an individualized nutritional plan is developed. Usually a soft diet or thick, cold fluids, such as milk shakes, are more easily tolerated.

Small, frequent meals or a commercial powder, such as Thick-It, added to liquids may assist the patient who has difficulty swallowing. Elevate the patient's head to allow easier swallowing and prevent aspiration. Remind UAP and teach the family to be careful when serving or feeding the patient. The SLP can be very helpful in recommending specific feeding strategies. Be sure that UAP record food intake daily or as needed. The patient loses weight because of altered food intake and the increased number of calories burned secondary to muscle rigidity. Teach the family to weigh the patient once a week so that adjustments to the diet can be made as indicated. As the disease progresses and swallowing becomes more of a problem, supplemental feedings become the main source of nutrition to maintain weight, with meals and other foods taken as the patient can tolerate.

Collaborate with the SLP if the patient has speech difficulties. Together with the health care team, patient, and family, develop a communication plan. The SLP teaches exercises to strengthen muscles used for breathing, speech, and swallowing. Teach the patient to speak slowly and clearly and to pause and take deep breaths at times during each sentence. Teach the family the importance of avoiding unnecessary environmental noise to increase the listener's ability to hear and understand the patient. Ask the patient to repeat words that the listener does not understand. Have the listener watch the patient's lips and nonverbal expressions for cues as to the meaning of conversation. Remind the patient to organize his or her thoughts before speaking and use facial expression and gestures, if possible, to assist with communication. In addition, he or she should exaggerate words to increase the listener's ability to understand. If the patient cannot communicate verbally, he or she can use alternative methods of communication, such as a communication board, mechanical voice synthesizer, computer, or personal digital assistant (PDA). The SLP assesses the ability to use these devices before a decision is made about which method to use. Some older patients may not want to use electronic methods to communicate.

Psychosocial Support. Although not all patients with PD have dementia, impaired cognitive function and memory deficits are common. Some patients also experience changes in gait and tremors that are uncontrollable. In the late stages of the disease, they cannot move without assistance, have difficulty talking, have minimal facial expression, and may drool. Patients often state that they are embarrassed, and they tend to avoid social events or groups of people. They should not be forced into situations in which they feel ashamed of their appearance. Encourage them to undertake activities that do not require small-muscle dexterity, such as light, modified aerobic exercises.

Collaborate with the social worker or case manager to help the family with financial and health insurance issues, as well as respite care or permanent placement if needed. Refer the patient and family to social and state agencies, as well as support groups as needed (e.g., the National Parkinson Foundation [www.parkinson.org]).

Teach the family to emphasize the patient's abilities or strengths and provide positive reinforcement when he or she meets expected outcomes. The patient, the family or significant other, and the rehabilitation team mutually set realistic expected outcomes that can be achieved.

The long-term management of PD presents a special challenge in the home care setting. A case manager may be required to coordinate interdisciplinary care and provide support for the patient and family. Impaired mobility affects the patient's daily lifestyle, including sexuality. The case manager or home care nurse uses a holistic approach to ensure that psychosocial, as well as physical, needs are addressed.

As the disease progresses and drug effectiveness decreases, refer the family to a palliative care organization or hospice. Referral sources can be obtained from the Center to Advance Palliative Care (www.capc.org), which advocates applying the principles of palliative care to chronic disease. Chapter 9 discusses palliative and hospice care in detail.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Informatics

A 68-year-old man reports shaking of his arms, hands, and head that he cannot control. He has also noticed that he walks more slowly now and thought it was part of the aging process. He is afraid that he won't be able to continue his job as an auto body worker because he says he can't live on his monthly Social Security money. His mother had Parkinson disease for many years and died of complications before she was 70. He decided he should see his family practice physician to discuss the changes he is experiencing. He is accompanied by his wife of 45 years; they have two children who live out of town.

1. As the patient's intake nurse, what questions might you include in his history?
2. What physical assessment will you perform and why?
3. The physician places the patient on Sinemet. You realize that you need to look up information about this drug to provide accurate health teaching. What reliable resources might you use?
4. What health teaching will you need to provide for this patient and his wife regarding his drug and other aspects of his illness?

Surgical Management

Several options are available if surgery for the patient with PD is needed. Surgery is a last resort when drugs are not effective in symptom management. The most common surgeries are stereotactic pallidotomy and thalamotomy, although newer surgical procedures are being tried. Deep brain stimulation may also be done.

Stereotactic Pallidotomy/Thalamotomy. **Stereotactic pallidotomy** (opening into the pallidum within the corpus striatum) can be a very effective treatment for controlling the symptoms associated with PD. First, the target area within the pallidum is identified by a CT or MRI scan. Next, the stereotactic head frame is placed on the patient. IV sedation is given, and a burr hole is made into the cranium. An electrode or cylindric rod is inserted into the target area. The target area

receives a mild electrical stimulation, and the patient's reaction is assessed for reduction of tremor and rigidity. If this result does not occur or if unexpected visual, motor, or sensory symptoms appear, the probe is repositioned. When the probe is in the ideal location, a permanent lesion (scarring) is made to destroy the tissue. The patient is monitored in the postanesthesia care unit (PACU) for about 1 hour and is then returned to the inpatient unit for continuing postoperative care.

As an alternative to stereotactic pallidotomy, the surgeon may perform a **thalamotomy** (opening into the thalamus of the brain for the stimulation) for treatment of tremor through thermocoagulation (high-frequency currents to destroy tissue) of brain cells. This procedure is effective for a limited number of patients. Because bilateral procedures have increased surgical complication rates, only unilateral (one-sided) surgery is done to benefit the side of the body that is most affected by the disease.

Deep Brain Stimulation. Deep brain stimulation (DBS) may be used when drug therapy is no longer effective in controlling the patient's symptoms. A thin electrode is implanted in the thalamus or subthalamus and then connected to a "pacemaker" that delivers electrical current to interfere with "tremor" cells. The electrodes are connected to an implantable pulse generator (IPG) that is placed underneath the skin in the patient's chest, similar to a cardiac pacemaker. The patient uses a magnet placed over the IPG to adjust the settings and to check the battery status. He or she continues on drug therapy after the procedure, but a smaller dosage may be needed to control symptoms.

Fetal Tissue Transplantation. Fetal tissue transplantation is an experimental and highly controversial ethical and political treatment. Fetal substantia nigra tissue, either human or pig, is transplanted into the caudate nucleus of the brain. Preliminary reports suggest that patients show clinical improvement in motor symptoms without dyskinesias after receiving the transplanted tissue. Long-term results are yet to be seen or studied.

ALZHEIMER'S DISEASE

Pathophysiology

Alzheimer's disease (AD), also known as *dementia*, *Alzheimer type (DAT)*, is a chronic, progressive, degenerative disease that accounts for 60% of the dementias occurring in people older than 65 years. It is less commonly seen in people in their 40s and 50s, which is referred to as *early dementia*, *Alzheimer type*, or *presenile dementia*, *Alzheimer type*. AD is manifested by loss of memory, judgment, and visuospatial perception and by a change in personality. Over time, the patient becomes increasingly cognitively impaired. Severe physical deterioration takes place, and death occurs as a result of complications of immobility.

The brain of the older adult usually weighs less and occupies less space in the cranial vault than does the brain of a younger person. Other changes in the brain that occur with aging include widening of the cerebral sulci, narrowing of the gyri, and enlargement of the ventricles. In the presence of AD, these normal changes are greatly accelerated. Brain weight is reduced further. Marked atrophy of the cerebral cortex and loss of cortical neurons occur. The cerebral sulci and fissures,

as well as the ventricles, are enlarged more than those of persons of the same age without AD. These areas of the brain are particularly affected:

- Precentral gyrus of the frontal lobe
- Superior temporal gyrus
- Hippocampus
- Substantia nigra

Microscopic changes of the brain found in people with AD include neurofibrillary tangles, amyloid-rich senile or neuritic plaques, and granulovascular degeneration. **Neurofibrillary tangles** are a classic finding at autopsy in the brains of patients with AD. They consist of tangled masses of fibrous tissue throughout the neurons. The same tangles and chemical changes are found in people with Down syndrome.

Neuritic plaques are composed of degenerating nerve terminals and are found particularly in the hippocampus, an important part of the limbic system. Deposited within the plaques are increased amounts of an abnormal protein called *beta amyloid*. These peptides have a tendency to accumulate and form the neurotoxic plaques found in the brain (McCance et al., 2010).

Although *vascular degeneration* occurs in the normally aging brain, its presence is significantly increased in patients with AD. Vascular degeneration accounts for at least partial loss of the ability of nerve cells to function properly. Cell deterioration and death may lead to hemorrhage. This pathologic change contributes to the mortality associated with this disorder.

In addition to the structural changes in the brain associated with AD, abnormalities in the neurotransmitters (acetylcholine [ACh], norepinephrine, dopamine, serotonin) may occur. High levels of beta amyloid are associated with reduced ACh by as much as 75%, which leads to a decrease in the amount of acetyltransferase in the hippocampus. This loss is major because the decrease in acetyltransferase interferes with cholinergic innervation to the cerebral cortex. This results in impaired cognition, recent memory, and the ability to acquire new memories. The exact role of reduced neurotransmitters in the development of AD is not well understood.

Etiology and Genetic Risk

The exact cause of AD is unknown. It is well established that *age, gender (women more than men), and family history are the most important risk factors* (Nussbaum et al., 2007). Several other theories and risk factors have been studied, including chemical imbalances, environmental agents, immunologic changes, and ethnicity/race. Compared with Euro-Americans, African Americans have a greater risk for

developing the disease and Hispanics tend to develop the disease earlier than other groups. The cause of these differences is not yet known.

Environmental agents, especially certain viruses such as herpes zoster and herpes simplex, and toxic metals such as zinc and copper have also been suggested as causes. Patients who have experienced a head injury or repeated head trauma (e.g., boxers) may be more at risk for AD, and at an earlier age, than others.

Incidence/Prevalence

There is a significant increase in both the incidence and prevalence of AD after 65 years of age, although it may affect anyone older than 40 years. The number of people in the United States with AD is estimated at 4.5 million. By the year 2050, that number is projected to increase to 14 million (Yaari & Correy-Bloom, 2007). AD has a significant impact on health care costs, including direct and indirect medical and social service costs.

Health Promotion and Maintenance

There are no proven ways to prevent AD. Current research activities are focusing on eating a balanced diet, eating dark-colored fruits and vegetables, using soy products, and consuming sufficient amounts of folate and vitamins B₁₂, C, and E. These substances have been reported to decrease the risk for developing AD, but study results are inconclusive and inconsistent. Walking, swimming, and other exercise not only increase tone and muscle strength but also may decrease mental decline in AD, as well as other dementias.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

The patient with Alzheimer's disease (AD) often presents with cognitive impairment, although many other disorders, drugs, and environmental factors can cause changes in cognition as well. A thorough history and physical examination are necessary to differentiate AD from other, possibly reversible causes (Table 44-4). Obtain information from family members or significant others because the patient may be unaware of the problems, denying their existence or covering them up. However, it is interesting to note that family members often do not recognize or may deny early changes in their loved one.

The most important information to be obtained is the onset, duration, progression, and course of the symptoms. Question the patient and the family about changes in memory or increasing forgetfulness and about the ability to perform ADLs. Ask about current employment status, work history, and ability to fulfill household responsibilities, including cleaning, grocery shopping, and preparing meals. Inquire about changes in driving ability, ability to handle routine financial transactions, and language and communication skills. In addition, document any changes in personality and behavior.

There is increasing evidence that an altered sense of smell is associated with the development of AD. Therefore ask about changes in the ability to smell or changes in the sense

GENETIC/GENOMIC CONSIDERATIONS

There is little doubt that many patients with AD had a genetic predisposition to the development of the disease, or familial AD (FAD). Most cases of early onset of AD are associated with genetic mutations.

Early-onset FAD (autosomal dominant AD) seems to be related to a rapid decrease in beta amyloid plaque formation, which is caused by defective genes, such as the beta-amyloid precursor gene (*APP*), the presenilin 1 gene (*PSEN1*), and the presenilin 2 gene (*PSEN2*). Late-stage AD research focuses on the role of apolipoprotein E (*APOE*) on chromosome 19 (Nussbaum et al., 2007; McCance et al., 2010). People with Down syndrome often develop dementia with clinical manifestations of AD. Down syndrome is a congenital condition resulting from abnormalities of chromosome 21.

TABLE 44-4 CAUSES OF COGNITIVE IMPAIRMENT IN THE OLDER ADULT

Neurologic Causes

- Vascular insufficiency
- Infections
- Trauma
- Tumors
- Normal-pressure hydrocephalus

Cardiovascular Causes

- Myocardial infarction
- Dysrhythmias
- Heart failure
- Cardiogenic shock
- Endocarditis

Pulmonary Causes

- Infection
- Pneumonia
- Hypoventilation

Metabolic Causes

- Electrolyte imbalance
- Acidosis/alkalosis
- Hypoglycemia/hyperglycemia
- Acute renal failure and chronic kidney disease
- Fluid volume deficit; urinary tract infections
- Hepatic failure

Drug Intoxication

- Misuse of prescribed medications
- Side effects of medications
- Incorrect use of over-the-counter medications
- Ingestion of heavy metals

Nutritional Deficiencies

- B vitamins
- Vitamin C
- Hypoproteinemia

Environmental Causes

- Hypothermia/hyperthermia
- Unfamiliar environment
- Sensory deprivation/overload

Psychological Causes

- Depression
- Anxiety
- Pain
- Fatigue
- Grief
- Paranoia

CHART 44-12 KEY FEATURES

Alzheimer's Disease**Early (Mild), or Stage I (first symptoms up to 4 years)**

- Independent in ADLs
- No social or employment problems initially
- Denies presence of symptoms
- Forgets names; misplaces household items
- Short-term memory loss; difficulty recalling new information
- Subtle changes in personality and behavior
- Loss of initiative; less engaged in social relationships
- Mild cognitive impairment, problems with judgment
- Decreased performance, especially when stressed
- Unable to travel alone to new destinations
- Decreased sense of smell

Middle (Moderate), or Stage II (2 to 3 years)

- Impairment of all cognitive functions
- Problems with handling or unable to handle money and finances
- Disorientation to time, place, and event
- Possible depression, agitated
- Increasingly dependent in ADLs
- Visuospatial deficits: difficulty driving, gets lost
- Speech and language deficits: less talkative, decrease in use of vocabulary, increasingly non-fluent, and eventually aphasic
- Incontinent
- Wandering; trouble sleeping

Late (Severe), or Stage III

- Completely incapacitated; bedridden
- Totally dependent in ADLs
- Motor and verbal skills lost
- General and focal neurologic deficits
- Agnosia (loss of facial recognition)

of smell. The history taking concludes with a review of the patient's medical history. Of particular importance is a history of head trauma, viral illness, or exposure to metal or toxic waste, as well as any family history of AD or Down syndrome.

Physical Assessment/Clinical Manifestations

Stages of Alzheimer's Disease. The clinical manifestations associated with AD can be grouped into three broad stages based on the progress of the disease (Chart 44-12). The patient does not necessarily progress from one stage to the next in an orderly fashion. A stage may be bypassed, or he or she may exhibit symptoms of one or several stages. Each patient exhibits different disease stages and clinical manifestations. Consequently, most authorities now use broader terms such as *early (mild)*, *middle (moderate)*, and *late (severe)* stages.

The primary focus of the neurologic assessment of patients with AD is to identify abnormalities in cognition, including language, personality, and behavior. Physical manifestations of neurologic impairment (seizures, tremors, or ataxia) tend to occur late in the disease process.

Changes in Cognition. **Cognition** refers to the ability of the brain to process, store, retrieve, and use information. Therefore assess the patient for deficits in these abilities:

- Attention and concentration
- Judgment and perception
- Learning and memory
- Communication and language
- Speed of information processing

One of the first symptoms of AD is short-term memory impairment. New memory and defects in information retrieval

result from dysfunction in the hippocampal, frontal, or parietal region. Alterations in communication abilities, such as **apraxia** (inability to use words or objects correctly), **aphasia** (inability to speak or understand), **anomia** (inability to find words), and **agnosia** (loss of sensory comprehension), are due to dysfunction of the temporal and parietal lobes. Frontal lobe impairment causes problems with judgment, an inability to make decisions, decreased attention span, and a decreased ability to concentrate. As the disease progresses to a later stage, the patient loses all cognitive abilities, is totally unable to communicate, and becomes less aware of the environment.

To assess cognitive status, the nurse or other health care provider can use one of several assessment tools. One of the most popular tools is Folstein's Mini-Mental State Examination (MMSE), also known as the "mini-mental." The MMSE assesses five major areas—orientation, registration, attention and calculation, recall, and speech-language (including reading). Fig. 44-2 lists examples of the questions asked on this test. The patient performs certain cognitive tasks that are scored and added together for a total score of 0 to 30. The lower the score is, the greater the severity of the dementia. It is not unusual for a patient with advanced AD to score below 5.

Although the MMSE is used frequently, the patient must be able to read. For the patient who cannot read or for a quicker screening test, the set test can be used, which is especially useful for the older adult. The patient is asked to name 10 items in each of four sets or categories: fruits, animals,

Orientation to Time

"What is the date?"

Registration

"Listen carefully, I am going to say three words. You say them back after I stop. Ready? Here they are... HOUSE (pause), CAR (pause), LAKE (pause). Now repeat those words back to me." [Repeat up to 5 times, but score only the first trial.]

Naming

"What is this?" [Point to a pencil or pen.]

Reading

"Please read this and do what it says." [Show examinee the words on the stimulus form.]

CLOSE YOUR EYES

A

FIG. 44-2 A, Examples of questions that are asked on the Mini-Mental State Examination. **B,** Copying is one of the tasks on the MMSE.

colors, and towns (FACT). Other categories can be used, if needed. The patient receives 1 point for each item for a possible maximum score of 40. Patients who score above 25 do not have dementia. Although this assessment is more comprehensive and easy to administer, it should not be used for patients with hearing impairments or speech and language problems.

Changes in Behavior and Personality. One of the most difficult aspects of AD that families, significant others, and health care professionals cope with is the behavioral changes that can occur in advanced disease. Assess the patient for:

- Aggressiveness, especially verbal and physical abusive tendencies
- Rapid mood swings
- Increased confusion at night or when light is not adequate (**sundowning**) or in excessively fatigued patients

The patient may wander and become lost or may go into other rooms to rummage through another's belongings. Hoarding or hiding objects is also common. For example, patients may hoard washcloths in the long-term care setting.

For some patients with dementia, emotional and behavioral problems occur with the primary disease. They may experience paranoia (suspicious behaviors), delusions, hallucinations, and depression. Document these behaviors, and ensure the patient's safety. (Refer to a mental health/behavior

health nursing textbook for a complete discussion of these disorders.)

Although drug therapy is not effective in treating dementia, certain drugs may help control the emotional and psychiatric manifestations (e.g., depression, anxiety, paranoia, aggression) associated with the primary disease.

Changes in Self-Management Skills. Observe for changes in the patient's self-management skills, such as:

- Decreased interest in personal appearance
- Selection of clothing that is inappropriate for the weather or event
- Loss of bowel and bladder control
- Decreased appetite or ability to eat

Over time, the patient becomes less mobile and muscle contractures develop. He or she eventually becomes totally immobile and requires total physical care. The patient is then unable to meet the human needs of mobility and cognition.

Psychosocial Assessment

In people with Alzheimer's disease (AD), the cognitive changes and biochemical and structural dysfunctions affect personality and behavior. In the early stage, patients often recognize that they are experiencing memory or cognitive changes and may attempt to hide the problems. They begin the grieving process because of anticipated loss,

experiencing denial, anger, bargaining, and depression at varying times. Older patients typically think the changes are part of “old age.”

When the patient and family receive the diagnosis, one or more family members may desire genetic testing. Support the patient's/family's decisions regarding testing, and assist them in finding credible resources for testing and professional genetics counseling.

As the disease progresses, patients begin to display major changes in emotional and behavioral affect. Of particular importance is the need for an assessment of the patients' reactions to changes in routine or environment. For example, a hospital admission is very traumatic for most patients with dementia. It is not unusual for them to exhibit a catastrophic response or overreact to any change by becoming excessively aggressive or abusive. This is referred to as *traumatic relocation syndrome*.

As patients become unaware of their behavior, the focus of the psychosocial assessment shifts to the family or significant others. The health care team assesses their ability to cope with the chronicity and progression of the disease and identifies possible support systems.

Laboratory Assessment

No laboratory test can confirm the diagnosis of AD. Definitive diagnosis is made on the basis of brain tissue examination at autopsy, which confirms the presence of neurofibrillary tangles and neuritic plaques.

Genetic testing, specifically for *apolipoprotein E4 (Apo E4)*, may be helpful as an ancillary test (not a predictive test) for the differential diagnosis of AD. *Amyloid beta protein precursor (soluble) (sBPP)* may be measured for patients to diagnose AD and other types of dementia. A decrease in the patient's sBPP in the cerebrospinal fluid (CSF) supports the diagnosis because the amyloid tends to deposit in the brain and is not circulating in the CSF (Pagana & Pagana, 2010).

A variety of other laboratory tests may be performed to rule out other treatable causes of dementia or delirium, including:

- Complete blood count (CBC)
- Serum electrolyte levels, blood urea nitrogen, and glucose
- Vitamin B₁₂ levels
- Folate levels
- Thyroid and liver function tests
- Serologic test for syphilis
- Toxicity screening tests; heavy metal screen
- Alcohol screening tests

Imaging Assessment

A CT, PET, or SPECT scan may be performed to rule out other causes of disease. The CT scan typically shows cerebral atrophy and ventricular enlargement, wide sulci, and shrunken gyri in the later stages of the disease. An MRI scan can also rule out other causes of neurologic disease. The PET and SPECT scans show a significant decrease in metabolic activity in the brains of people with AD.

Other Diagnostic Assessment

The electroencephalogram (EEG) shows slow-wave delta activity seen in the second and third stages of AD. To more clearly identify the nature and extent of the patient's cognitive

impairment, the neurologist or psychologist administers several neuropsychological tests. The tests selected depend on clinician preference and the ability of the patient to participate in testing. All of the tests focus on cognitive ability and may be repeated over time to measure changes.

ANALYSIS

The priority problems for patients with Alzheimer's disease (AD) are:

1. Chronic Confusion related to neuronal degeneration in the brain
2. Risk for Injury related to wandering or elder abuse
3. Caregiver Role Strain related to the patient's prolonged progression of disability and the patient's increasing care needs

PLANNING AND IMPLEMENTATION

The priority for interdisciplinary care is safety! Chronic confusion and physical deficits place the patient with AD at a high risk for injury.

Managing Chronic Confusion

Planning: Expected Outcomes. In the very early stages of the disease, the patient with AD is expected to maintain the ability to perform complex mental processes. As the disease progresses, patients cannot meet this outcome. Instead, the desired outcome is to maintain cognitive function for as long as possible to keep patients safe and increase their quality of life.

Interventions Although drug therapy may be used for patients with AD, nonpharmacologic interventions are the main focus of patient-centered collaborative management. Teach family members and significant others about the importance of being consistent in following the plan of care.

Nonpharmacologic Management. The health care provider should answer the patient's questions truthfully concerning the diagnosis of AD. In this way, the patient can more fully participate in the interdisciplinary plan of care. Interventions are the same whether he or she is cared for at home, in an adult day-care center, in an assisted-living center, in a long-term care facility, or in a hospital admitted with another medical condition. *The patient with memory problems always benefits best from a structured and consistent environment.*

Many factors, including physical illness and environmental factors, can exacerbate (worsen) the clinical manifestations of AD (Table 44-5). The patient with AD frequently has other medical problems such as cardiovascular disease, arthritis, renal insufficiency, and pulmonary disease. Changes in vision and hearing also may be present. Managing these conditions helps the patient's functional abilities.

TABLE 44-5 FACTORS THAT CAN WORSEN ALZHEIMER'S DISEASE

• Stroke	• Impaired renal function
• Subdural hematoma	• Impaired hepatic function
• Space-occupying lesion	• Infection
• Decrease in blood supply to the brain	• Impaired vision and hearing
• Myocardial infarction	• Sudden changes in surroundings
• Dysrhythmias	• Pain and discomfort
• Hypoglycemia	• Drugs
	• Physical or chemical restraint

Approaches to managing the patient who has Alzheimer's disease include:

- Cognitive stimulation and memory training
- Structuring the environment
- Orientation and validation therapy
- Promoting self-management
- Promoting bowel and bladder continence
- Promoting communication

The purpose of *cognitive stimulation and memory training* is to reinforce or promote desirable cognitive function and facilitate memory. An individualized cognitive therapy program may provide some benefit to the patient.

As the disease progresses, the patient may experience **prosopagnosia**, an inability to recognize oneself and other familiar faces. Encourage the family to provide pictures of family members and close friends that are labeled with the person's name on the picture. In addition, advise the family to reminisce with the patient about pleasant experiences from the past. Use *reminiscence therapy* while assisting the patient with ADLs or performing a treatment or assessment. Refer to a personal item in the room to help the patient begin to talk about its meaning in the present and in the past.

It is not unusual for the patient to talk to his or her image in the mirror. This behavior should be allowed as long as it is not harmful. If the patient becomes frightened by the mirror image, remove or cover the mirror. In some long-term care or assisted-living settings, a picture of the patient is placed on the room door to help with facial recognition and to help the patient locate his or her room. This picture also helps the staff locate the patient in case of elopement (running away).

Teach the family to keep environmental distractions and noise to a minimum. The patient's home, hospital room, or nursing home room should not have pictures on the wall or other decorations that could be misinterpreted as people or animals that could harm the patient. An abstract painting or wallpaper might look like a fire or an explosion and scare the patient. The room should have adequate, nonglare lighting and no potentially frightening shadows.

In addition to disturbed sleep, other negative effects of high noise levels include decreased nutritional intake, changes in blood pressure and pulse rates, and feelings of increased stress and anxiety. The patient with AD is especially susceptible to these changes and needs to have as much undisturbed sleep at night as possible. Fatigue increases confusion and behavioral manifestations such as agitation and aggressiveness.

! NURSING SAFETY PRIORITY

Action Alert

When a patient with Alzheimer's disease is in a new setting or environment, collaborate with the staff and admitting department to select a room that is in the quietest area of the unit and away from obvious exits, if possible. A private room may be needed if the patient has a history of agitation or wandering. The television should remain off unless the patient turns it on or requests that it be turned on.

Objects such as furniture, a hairbrush, and eyeglasses should be kept in the same place. Establish a daily routine, and follow it as much as possible. Arrange for a communication board for scheduled activities and other information to promote orientation such as the day of the week, the month,

and the year. Pictures of people familiar to the patient can also be placed on this board.

Explain changes in routine to the patient before they occur, repeating the explanation immediately before the changes take place. Clocks and single-date calendars also help the patient maintain day-to-day orientation to the environment in the early stages of the disease process. *For the patient with early disease, reality orientation is usually appropriate.* Teach family members and health care staff to frequently reorient the patient to the environment. Remind the patient what day and time it is, where he or she is, and who you are.

For the patient in the later stages of AD, reality orientation does not work and often increases agitation. *The health care team uses validation therapy for the patient with moderate or severe AD. In validation therapy, the staff member recognizes and acknowledges the patient's feelings and concerns.* For example, if the patient is looking for a deceased mother, ask him or her to talk about what Mother looks like and what she might be wearing. This response does not argue with the patient but also does not reinforce the patient's belief that Mother is still living.

As the disease progresses, altered thought processes affect the *ability to perform ADLs*. Encourage the patient to perform as much self-care as possible and to maintain independence in daily living skills as long as possible. For example, in the home setting, complete clothing outfits that can be easily removed and put on (e.g., shirt, slacks, underwear, socks) and placed on a single hanger are preferred for patient selection. When possible, the patient should participate in meal preparation, grocery shopping, and other household routines. Many patients cannot make purposeful movements as the disease progresses.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client with Alzheimer's disease asks the nurse to find her mother, who is deceased. What is the nurse's best response?

- "Your mother died over 20 years ago."
- "I'll find your mother as soon as I finish passing meds."
- "What did your mother look like?"
- "I'll ask your daughter to find your mother."

Collaborate with the occupational and physical therapists to provide a complete evaluation and assistance in helping the patient become more independent. Adaptive devices, such as grab bars in the bathtub or shower area, an elevated commode, and adapted eating utensils, may enable him or her to maintain independence in grooming, toileting, and feeding. The physical therapist prescribes an exercise program to improve physical health and functionality.

The patient may remain continent of bowel and bladder for long periods if taken to the bathroom or given a bedpan or urinal every 2 hours. Toileting may be needed more often during the day and less frequently at night. Unlicensed assistive personnel (UAP) or home caregiver encourages the patient to drink adequate fluids to promote optimal voiding. A patient may refuse to drink enough fluids because of a fear of incontinence. Assure the patient that he or she will be toileted on a regular schedule to prevent incontinent episodes.

When patients with AD are in the hospital or other unfamiliar place, they may get out of bed unassisted during the night and fall while trying to locate the bathroom. Do not use siderails unless absolutely necessary. If the patient climbs over the siderail and falls, the injury is likely to be worse than if the bed had been left in the lowest position and the siderails left down (Cotter & Evans, 2008). In both acute and long-term care settings, siderails may be considered a physical restraint and are not used unless they increase patient mobility. Chapter 3 discusses fall prevention in detail.

Maintain a clear path between the bed and bathroom at all times. For patients who are too weak to walk to the bathroom, a bedside commode may be used. Some patients may void in unusual places, such as the sink or a wastebasket. As a reminder of where they should toilet, place a picture of the commode on the bathroom door. Depending on written signs for identification is useless because most patients lose their ability to read as the disease progresses.

Use **redirection** by attracting the patient's attention to promote communication. Keep the environment as free from distractions as possible. Speak directly to the patient in a distinct manner. Sentences should be clear and short. Remind the patient to perform one task at a time, and allow sufficient time for completion. It may be necessary to break each task down into many small steps (Chart 44-13).

As the disease progresses, the patient is unable to perform tasks when asked. Show the patient what needs to be done, or provide cues to remind him or her how to perform the task. When possible, explain and demonstrate the task that the patient is asked to perform.

Patients with AD typically have specific speech and language problems, such as:

- **Aphasia** (difficulty speaking and understanding language)
- **Anomia** (difficulty finding words to name an object)
- **Apraxia** (difficulty recognizing words)

Recognize that emotional and physical behaviors may be a form of communication. Interpret the meaning of these behaviors to address them. For example, restlessness may indicate urinary retention, pain, infection, or hypoxia (lack of oxygen to the brain).

Drug Therapy. **Cholinesterase inhibitors** are drugs approved for treating AD symptoms. They work to improve

cholinergic neurotransmission in the brain by delaying the destruction of acetylcholine (ACh) by the enzyme *acetylcholinesterase*. This action slows the onset of cognitive decline in some patients. None of these drugs alters the course of the disease. Examples include donepezil (Aricept), galantamine (Reminyl), and rivastigmine (Exelon).

Memantine (Namenda) is the first of a new class of drugs that is a low to moderate affinity **N-methyl-D-aspartate (NMDA) receptor antagonist**. Overexcitation of NMDA receptors by the neurotransmitter *glutamate* may play a role in AD. This drug therefore blocks excess amounts of glutamate that can damage nerve cells. It is indicated for advanced AD and has been shown to slow the pace of deterioration. Namenda may help maintain patient function for a few months longer. Some patients also have improved memory and thinking skills. This drug can be given with donepezil (Aricept), a cholinesterase inhibitor.

Some patients with AD develop depression and may be treated with **antidepressants**. Selective serotonin reuptake inhibitors (SSRIs), such as paroxetine (Paxil) and sertraline (Zoloft), are usually prescribed. Tricyclic antidepressants, such as amitriptyline (Elavil, Levate ☛), should not be used because of their anticholinergic effect, especially for older adults. Anticholinergic drugs frequently cause serious side effects, including increased confusion, urinary retention, and constipation.

Psychotropic drugs, also called *antipsychotic* or *neuroleptic drugs*, should be reserved for patients with emotional and behavioral health problems that sometimes accompany dementia, such as hallucinations and delusions. In clinical practice, however, these drugs are sometimes incorrectly used for agitation, combativeness, or restlessness. Psychotropic drugs are considered chemical restraints because they decrease mobility and patients' self-management ability. Therefore most geriatricians recommend that these drugs be used as a last resort and with caution in low doses for a specific emotional or behavioral health problem. The specific drug prescribed depends on side effects, the condition of the patient, and expected outcomes. Follow agency policy and The Joint Commission standards concerning the use of chemical restraints (National Patient Safety Goals).

Preventing Injury

Planning: Expected Outcomes. The patient with Alzheimer's disease (AD) is expected to remain free from physical harm and not injure anyone else.

Interventions. Many patients with AD tend to wander and may easily become lost. In later stages of the disease, some patients may become severely agitated and physically or verbally abusive to others. Teach the family the importance of a patient identification badge or bracelet. The badge should include how to contact the primary caregiver. In an inpatient setting, check the patient frequently and place him or her in a room that can be monitored easily. The room should be away from exits and stairs. Some health care agencies place large stop signs or red tape on the floor in front of exits. Others have installed alarm systems to indicate when a patient is opening the door or getting out of a bed or chair.

Teach the family to enroll the patient in the Safe Return Program—a national, government-funded program of the Alzheimer's Association (www.alz.org) that assists in the identification and safe, timely return of people with

CHART 44-13 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Promoting Communication with the Patient with Advanced Alzheimer's Disease

- Ask simple, direct questions that require only a "yes" or "no" answer if the patient can communicate.
- Provide instructions with pictures in a place that the patient will see if he or she can read them.
- Use simple, short sentences and one-step instructions.
- Use gestures to help the patient understand what is being said.
- Validate the patient's feelings.
- Limit choices; too many choices cause frustration and increased confusion.
- Never assume that the patient is totally confused and cannot understand what is being communicated.
- Try to anticipate the patient's needs and interpret nonverbal communication.

dementia. The program includes registration of the patient and a 24-hour hotline to be called to assist in finding a lost patient. If a patient wanders and becomes lost, the family (or health care institution) should immediately notify the police department. An up-to-date picture of the patient makes it easier for local authorities, the public, and neighbors to identify the missing patient. Devices using radio wave beacons and a global positioning system (GPS) have been developed to help families and law enforcement officials find a lost patient more easily. These devices include shoes with a GPS unit implanted, jewelry that is hard to remove, and bracelets. Caution families that these devices are not foolproof. Just like cell phones, there are some areas where the signal from the patient may not be picked up easily if at all.

Restlessness may be decreased if the patient is taken for frequent walks. If the patient begins to wander, redirect him or her. For example, if the patient insists on going shopping for clothes, the patient is redirected to his or her closet to select clothing that will not be recognized as his or her own. This type of activity can be repeated a number of times because the patient has lost short-term memory. Best practices for preventing and managing wandering are listed in [Chart 44-14](#).

In any setting, keep the patient busy with structured activities. In a health care agency, an activity therapist or volunteer may work with patients as a group or individually to determine the type of activity that is appropriate for the stage of the disease. Puzzles, board games, and art activities are often appropriate. Music and art therapy are becoming very popular in acute and long-term care for patients with dementia.

NURSING SAFETY PRIORITY

Action Alert

In inpatient health care agencies, apply physical restraints such as waist belts and geri-chairs with lapboards only as a last resort because they often increase patient restlessness and cause agitation. Federal regulations in long-term care facilities in the United States mandate that all residents have the right to be free of both physical and chemical restraints. In addition, all health care agencies accredited by The Joint Commission are required to use alternatives to restraints before resorting to any physical or chemical restraint.

CHART 44-14 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Approaches to Prevent and Manage Wandering in Hospitalized Patients

- Identify the patients most at risk for wandering through observation and history provided by family.
- Provide appropriate supervision, including frequent checks (especially at shift-change times).
- Place the patient in an area that provides maximum observation, but not in the nurses' station.
- Use family members, friends, volunteers, and sitters as needed to monitor the patient.
- Keep the patient away from stairs or elevators.
- Do not change rooms to prevent increasing confusion.
- Avoid physical or chemical restraints.
- Assess and treat pain.
- Use re-orientation methods and validation therapy, as appropriate.
- Provide frequent toileting and incontinence care as needed.
- If possible, prevent overstimulation, such as excessive noise; use soft music and nonglare lighting if possible.

Patients with AD may be injured because they cannot recognize objects or situations as harmful. Remove or secure all potentially dangerous objects (e.g., knives, drugs, cleaning solutions). Patients are often unaware that their driving ability is impaired and usually want to continue this activity even if their driver's license has been suspended or they are unsafe. Automobile keys must be secured, but the patient should be told why they were taken. (See [Chapter 3](#) for more discussion on older adult driving.)

Late in the disease process, the patient may experience seizure activity. If he or she is cared for at home, teach caregivers what action to take when a seizure occurs. (See discussion of [Interventions](#) on p. 933 in the [Seizures and Epilepsy](#) section.)

Talking calmly and softly and attempting to redirect the patient to a more positive behavior or activity are effective strategies when he or she is agitated. Use calm, positive statements, and reassure the patient that he or she is safe. Statements such as "I'm sorry that you are upset," "I know it's hard," and "I will have someone stay with you until you feel better" may help.

Actions to *avoid* when the patient is agitated include raising the voice, confrontation, arguing, reasoning, taking offense, or explaining. Teach the caregiver to not show alarm or make sudden movements out of the person's view. If the patient remains agitated, ensure his or her safety and leave the room after explaining that you will return later. Frequent visual checks must be done during this time. If the patient is connected to any type of tubing or other device, he or she may try to disconnect it or pull it out. These devices should be used cautiously in the patient with dementia. If IV access, for example, is needed, the catheter or cannula is placed in an area that the patient cannot easily see or it should be covered.

Another way to manage this problem is to provide a diversion. For example, if the patient is doing an activity or holding an item such as a stuffed animal or other special item, he or she might be less likely to pay attention to medical devices. Additional strategies to minimize behavioral problems, especially at home, are listed in [Table 44-6](#).

Drugs may be used only if other modalities fail to control the patient's agitation and the behavior may lead to the patient or other being harmed. For example, risperidone (Risperdal) and lorazepam (Ativan) should be used with caution because of their significant potential side effects (e.g., sedation, increased confusion).

Patients who are cared for at home are at high risk for neglect or abuse. The Joint Commission requires all patients to be assessed for neglect and abuse on admission to a health care facility. Patients with mild AD may not report these concerns for fear of retaliation. Those with severe AD may not have the ability to report the abuse. Asking questions such as "Who cooks for you?" "Do you get help when you need it?" or "Do you wait long for help to the bathroom?" may be less

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which nursing intervention is appropriate when caring for a client with Alzheimer's disease?

- Provide a large clock and calendar.
- Place the client in a geri-chair to prevent wandering.
- Insert a urinary catheter to prevent incontinence.
- Place the client in the nurses' station.

TABLE 44-6 MINIMIZING BEHAVIORAL PROBLEMS FOR PATIENTS WITH ALZHEIMER'S DISEASE AT HOME

Carefully evaluate the patient's environment.

- Ensure environment is safe:
 - Remove throw rugs.
 - Consider replacing tile floors with non-slippery floors.
 - Arrange furniture and room decorations to maximize the patient's safety when walking.
 - Minimize clutter in all rooms in and outside of the house.
 - Install nightlights in patient's room, bathroom, and hallway.
 - Install and maintain smoke alarms, fire alarms, and natural gas detectors.
- Install safety devices for the bathroom.
- Install alarm system or bells on outside doors; place safety locks on doors and gates.
- Ensure that door locks cannot be easily opened by the patient.

Assist the patient to remain oriented as long as possible.

- Place single-date calendars in patient's room and in kitchen.
- Use large-face clocks with a neutral background.

Communicate with the patient based on his or her ability to understand.

- As the disease progresses, use simple language and explain activity before the patient needs to carry it out.
- Break complex tasks down to simple steps.

Encourage the patient to be as independent as possible in ADLs.

- Place complete outfits for the day on hangers; have the patient select one to wear.
- Develop and maintain a predictable routine (e.g., meals, bedtime, morning routine).

When a problem behavior occurs, use distraction to divert patient to another activity.

Minimize excessive stimulation.

- Take the patient on outings when crowds are small.
- If crowds cannot be avoided, minimize the amount of time the patient is present in a crowd. For example, at family gatherings, provide a quiet room for the patient to rest throughout the visit.

Arrange for a day-care program if possible.

Register the patient with the Alzheimer's Association Safe Return Program (www.alz.org).

CHART 44-15 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Reducing Caregiver Stress**

- Maintain realistic expectations for the person with Alzheimer's disease (AD).
- Take each day one at a time.
- Try to find the positive aspects of each incident or situation.
- Use humor with the person who has AD.
- Use the resources of the Alzheimer's Association, including attending local support group meetings.
- Explore alternative care settings early in the disease process for possible use later.
- Establish advance directives with the AD patient early in the disease process.
- Set aside time each day for rest or recreation away from the patient, if possible.
- Seek respite care periodically for longer periods of time.
- Take care of yourself by watching your diet, exercising, and getting plenty of rest.
- Be realistic about what you or they can do, and accept help from family, friends, and community resources.
- Use relaxation techniques.

or her health care provider or should seek one on his or her own. It is not unusual for the caregiver to refuse to accept help from others, even for a few brief hours. Initially, the caregiver may be more comfortable accepting help for just a few minutes a day so he or she could shower, enjoy a cup of tea, or take a brief walk. Some caregivers find that eventually they need to place their loved one into a respite setting or unit so that they can re-energize.

Refer all families to their local chapter of the Alzheimer's Association (www.alz.org) in the United States or to the Alzheimer Society of Canada (www.alzheimer.ca). These organizations provide information and support services to patients and their families, including seminars, audiovisual aids, and publications.

Community-Based Care**Home Care Management**

AD is a chronic, progressive condition that eventually leaves the patient completely disoriented and totally dependent on others for all aspects of care. In the early stages, patients may be cared for at home with little need for outside intervention. Whenever possible, the patient and family should be assigned a case manager who can assess their needs for health care resources and find the best placement throughout the continuum of care.

The patient usually begins to withdraw from friends and social events as memory impairment and personality and behavior changes occur. The family may begin to decrease their own social activities as the demands of the patient's care take more of their time. Emphasize to the family the importance of maintaining their own social contacts and leisure activities. Many family members experience caregiver stress, which affects their physical, mental, and emotional health.

Chart 44-15 lists strategies for reducing caregiver stress. **Chapter 3** discusses caregiver role strain and interventions in more detail.

It is now possible in most areas of the United States and Canada for families to arrange respite care. The patient may

stressful for the patient to answer. **Chapter 3** discusses this problem in detail.

Managing Caregiver Role Strain

Planning: Expected Outcomes. The family or other caregivers of the patient with Alzheimer's disease (AD) are expected to plan time to care for themselves to promote a reasonable quality of life and satisfaction.

Interventions. The patient with moderate or severe AD requires continual 24-hour supervision and caregiving. Severe cognitive changes leave the patient unable to manage finances, property, or personal care. The family needs to seek legal counsel regarding the patient's competency and the need to obtain guardianship or a durable medical power of attorney when necessary. Refer the family to the local AD support group for literature and information concerning the disease and related problems.

Family members and other caregivers must be aware of their own health and stress levels. Signs of stress include anger, social withdrawal, anxiety, depression, lack of concentration, sleepiness, irritability, and health problems. When signs of stress occur, the caregiver should be referred to his

be placed in a respite facility or nursing home for the weekend or for several weeks to give the family a rest from the constant care demands. The family may also be able to obtain respite care in the home through a home care agency or assisted-living facility. Remind the family that respite care is for a short period—it is not permanent placement. Some health care agencies have opened adult day-care centers or specialty units for patients with AD. In the day-care center, patients spend all or part of the day at the facility and participate in activities as their condition permits. Although these centers are usually open only on weekdays, this arrangement allows the caregiver to work or participate in other activities. If patients require 24-hour care, they may be placed in a specialty unit of a long-term care or assisted-living facility.

Teach the family how to be prepared in case the patient becomes restless, agitated, abusive, or combative. In addition, the family can learn how to use reality orientation or validation therapy, depending on the stage of the disease.

Teaching for Self-Management

Usually patients with AD are cared for in the home until late in the disease process unless they can afford private-pay care. Because health insurance coverage in the United States and family finances may not be sufficient to cover the services of a private duty nurse or home care aide, family members typically provide the care. The patient plan of care developed by the nurse or case manager, in conjunction with the family, must be reasonable and realistic for the family to implement.

Review how to assist with bathing, dressing, toileting, and other self-management activities. The occupational therapist teaches the family and the patient how to use adaptive equipment, such as a brace, a sling, a cane, or modified eating utensils. The patient may have difficulty chewing, swallowing, or tasting foods and may not be able to eat without assistance.

The family and the dietitian should develop a diet plan to increase the patient's nutritional intake. In the late stage of AD, the patient's intake often decreases and he or she loses weight.

Provide information to the family on what to do in the event of a seizure and how to protect the patient from injury. Instruct them to notify the health care provider if the seizure is prolonged or if the patient's seizure pattern changes.

Review with the family or other caregiver the name, time, and route of administration; the dosage; and the side effects of all drugs. Remind the family to check with the health care provider before using any over-the-counter drugs or herbs because they may interact with prescribed drug therapy.

Emphasis is placed on the need for the patient to have an established exercise program to maintain mobility for as long as possible, as well as to prevent complications of immobility. In collaboration with the family, the physical therapist (PT) develops an individualized exercise program. The PT may continue to work with the patient at home until goals are achieved, depending on the payer source.

Remind the family or other caregiver to take special precautions to maintain the patient safely at home. The environment must be uncluttered, consistent, and structured. All hazardous items (e.g., cooking range and oven, power tools) are removed, secured, or "locked out." All electrical sockets not in use should be covered with safety plugs. Teach families to install handrails and grab bars in the bathroom. Handrails should be along all stairways, and a guardrail should be placed around porches or open stairwells. Because the patient

may have a tendency to wander, especially at night, the family may want to install alarms to all outside doors, the basement, and the patient's bedroom. All outside and basement doors should have deadbolt locks to prevent the patient from going outside unsupervised. Remind the family to adjust the temperature of the water to prevent accidental burns. Nightlights should be used in the patient's bedroom, hallway, and bathroom to prevent fear and to help with orientation.

Health Care Resources

When the patient can no longer be cared for at home, referral to an assisted-living or long-term care facility may be needed. Early in the course of the disease, advise the family that placement might be needed in the late stages of the disease or sooner. This allows the family to begin to search for an appropriate facility before a crisis develops and immediate placement is needed. A number of facilities specialize in the care of patients with AD and other dementias. These units generally have a high staff-to-patient ratio and are architecturally designed to meet the special needs of this type of patient. The national office of the Alzheimer's Association publishes an outline of criteria for a dementia unit. In the advanced stage of the disease, the patient may need referral to hospice services for total care. (See the discussion of end-of-life and hospice care in Chapter 9.)

EVALUATION: OUTCOMES

Evaluate the care of the patient with Alzheimer's disease (AD) based on the identified priority patient problems. The expected outcomes include that the patient and/or family will:

- Have the ability to maintain complex mental processes (*early AD*) or maintain current cognitive status
- Remain free from injury and have a safe home environment
- Sleep through the night and be awake at appropriate times
- Meet basic human needs (e.g., nutrition, mobility)

The caregiver will have a positive perception of his or her health status and life circumstances. Specific indicators for these outcomes are listed for each priority problem in the Planning and Implementation section (see earlier).

HUNTINGTON DISEASE

Pathophysiology

Huntington disease (HD), sometimes referred to as *Huntington's disease*, is an hereditary disorder transmitted as an autosomal dominant trait at the time of conception. This movement disorder causes both neurologic and behavioral symptoms that usually begin between the ages of 30 and 50 years and worsen during the next 1 to 2 decades. Patients typically die from pneumonia, heart failure, or other complication of immobility (*Huntington's Disease Society of America [HDSA], 2010*).

It is estimated that 30,000 people in the United States have HD, and another 20,000 to 50,000 are thought to carry the gene (*HDSA, 2010*). Men and women are equally affected at a highly productive time in life. The clinical onset of HD is gradual. The two main symptoms of the disease are progressive mental status changes, leading to dementia, and

GENETIC/GENOMIC CONSIDERATIONS

Huntington disease is a single gene disorder caused by a mutation in the HD gene (*IT15*) located on chromosome 4. The mutation is a multiple repeat of the specific base triplet CAG, increasing the length of the gene. An autosomal dominant trait with high penetrance means that a person who inherits just one mutated allele has nearly a 100% chance of developing the disease (McCance et al., 2010). This gene mutation has different expressions, depending on whether it is inherited from the mother or the father. People who inherit the mutation from their father have an earlier onset and a shorter life expectancy than do those who inherit from their mother. In addition, there is some variation in the disease, depending on the size (length) of the mutation. The longer the mutation, the more severe the disease is at an earlier age.

choreiform movements (rapid, jerky movements) in the limbs, trunk, and facial muscles. Dementia is related to the destruction of neurons within the cerebral cortex. It may also be associated with excessive amounts of dopamine found within the cerebral cortex and limbic systems of those affected. Two structures within the basal ganglia are involved in the development of HD: the caudate nucleus and the putamen. Both structures have close connections to the cerebral cortex and are closely associated with neurotransmitters. Neurotransmitters are secreted at the synapse, or junction, of one neuron with another, and it is through their specific excitation or inhibition of neurons that fine, controlled, integrated motor activity occurs.

In HD, there is a decrease in the amount of *gamma-aminobutyric acid* (GABA), an inhibitory neurotransmitter in the basal ganglia. GABA depletion causes increased activity of the thalamus and other parts of the brain. There may also be an increase in *glutamate*, a major excitatory neurotransmitter. The result of these chemical changes in the brain is brisk, jerky, purposeless movements, particularly of the hands, face, tongue, and legs, which the patient cannot stop (McCance et al., 2010).

There are three stages of HD, each lasting roughly 5 years, corresponding to the average 15-year course of the disease. Stage 1 is the onset of neurologic or psychological symptoms. Stage 2 is characterized by an increasing dependence on others for care. Stage 3 results in loss of independent function.

The diagnosis of HD is made on the basis of a family history of the disease and clinical assessment. The triad of dominant inheritance, choreoathetosis (neuromuscular symptoms), and dementia is the hallmark of the disease. The symptoms exhibited by the patient vary in range and severity, age of onset, and rate of progression. Observe for clinical manifestations, which include chorea (jerky movements), poor balance, hesitant or explosive speech, dysphagia (difficulty swallowing), impaired respiration, and bowel and bladder incontinence. Mental status changes include decreased attention span, poor judgment, memory loss, personality

changes, and dementia (later in the disease process). Perform a complete neurologic assessment.

PATIENT-CENTERED COLLABORATIVE CARE

There is no known cure or treatment for HD. The only way to prevent transmission of the gene is for those affected to avoid having biologic children. Genetic counseling is important for children of patients with the disease. People at risk for the disease can be tested to determine whether the gene mutation is present. Before the testing procedure is undertaken, counseling is necessary to ensure that the patient has voluntarily decided in favor of testing and is not being pressured by family or friends. In addition, counseling helps determine whether the benefits of knowing the results outweigh the risks of a positive result (e.g., depression or suicide).

The first drug to be approved to decrease chorea associated with HD is tetrabenazine (Xenazine). It is given orally and is thought to work by depleting the monoamines (e.g., dopamine, serotonin) from nerve terminals. In some patients, it may increase the risk for suicide ideations and depression. Be sure to teach them and their families to report early signs of depression, including sleeplessness, decreasing appetite, and mood changes.

In other patients, psychotropic agents may be used to manage movement abnormalities that interfere with ADLs or are functionally disabling. They are also used to help control agitation, hallucinations, or psychotic delusions. Drug therapy may be used to treat other symptoms such as depression, anxiety, or obsessive-compulsive behaviors. Many of the drugs used to treat HD may cause side effects that may be difficult to differentiate from signs of HD.

A number of clinical trials are being conducted to find other drugs or supplements that may decrease HD symptoms. Examples include the CoQ10 enzyme, growth factors, glutamate blockers, and antidepressants, such as sertraline (Zoloft).

The care of the patient with HD is managed by the collaborative efforts of the family and health care team and includes:

- Speech-language pathologist (SLP) who helps with communication, swallowing, and drooling
- Dietitian who plans meals based on the SLP's recommendations and the patient's likes and dislikes
- Physical and occupational therapists who determine exercise conditioning and assistive devices
- Nurses or home health care aides who provide supportive care
- Case manager and social worker who coordinate care and help with referrals to community resources (e.g., Huntington Disease Society of America [www.hdsa.org]) and health care agencies for placement as needed

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing impaired mobility and cognition as a result of an acute CNS infection or chronic brain disorder?

- Headache
- Acute or chronic confusion

- Sleepiness or lethargy
- Inability to perform ADLs
- Inability to ambulate or alteration in gait
- Continuing weight loss
- Inability to communicate effectively

NURSING CONCEPT REVIEW—cont'd

- Report of photophobia or phonophobia
- One or more seizures
- Extremity tremors, rigidity, or jerky movements

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired mobility and cognition as a result of an acute CNS infection or chronic brain disorder?

Perform and interpret physical assessment, including:

- Assessing neurologic status, especially level of consciousness (LOC) and mental status
- Taking vital signs (high fever may indicate infection)
- Performing a comprehensive pain assessment
- Assessing ability to communicate
- Assessing nutritional status

Respond by:

- Notifying health care provider or Rapid Response Team if seizure or sudden change in LOC or mental status

- Ensuring an adequate airway
- Protecting patient from injury
- Managing pain
- Giving oxygen (for status epilepticus)
- Reorienting patient
- Assisting with ADLs if needed
- Collaborating with health care team members (e.g., PT, OT, SLP, dietitian)

On what should you REFLECT?

- Think about how you responded.
- Continue to monitor for improving mental status and changes in LOC.
- Assess triggers or other causes for acute event.
- Develop teaching plan for patient and family for self-management.
- Think about what resources the patient and family may need.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- For a patient having a tonic-clonic or complete partial seizure, protect him or her from injury.
- Implement interventions for seizures as listed in [Chart 44-5](#). Patients with status epilepticus have a life-threatening complication. Lorazepam and diazepam are the major drugs used for this emergency.
- Collaborate with the health care team in discharge planning and health teaching for patients who have chronic neurodegenerative diseases such as Alzheimer's disease.
- Help patients and families identify community resources for chronic brain disorders, including the Alzheimer's Association and the National Parkinson Foundation.
- Observe patients with Alzheimer's disease closely because they tend to wander and make inappropriate decisions. Safety is a priority for these patients.

Health Promotion and Maintenance

- Teach patients with migraine headaches about triggers that could cause an attack, such as caffeine, wine, and pickled products.
- Teach patients with cluster headaches about precipitating factors, such as anger episodes, excitement, and excessive physical activity.
- In addition to prescribed drug therapy, encourage patients with headaches to use complementary and alternative

therapies to help relieve pain, such as ice, darkened room, and relaxation techniques.

- Teach the patient with epilepsy the importance of continuing prescribed antiepileptic drugs (AEDs), even if he or she is seizure-free. Additional instructions for the patient and family are listed in [Chart 44-4](#).
- Encourage people who are in areas of high population density, such as college dormitories and crowded living areas, to become immunized against meningococcal meningitis. Teach older adults and those with chronic illness to have influenza and pneumonia vaccines.
- Teach people who enjoy outdoor activities to avoid areas where mosquitoes and ticks are likely to populate, especially near lakes and wooded areas. If they are in contact with these areas, remind them (especially older adults) to use insect repellent and keep skin exposure at a minimum.

Psychosocial Integrity

- Remind caregivers of patients with chronic neurologic diseases, such as Alzheimer's disease, to find ways to cope with their own stress to remain physically and psychologically healthy, as suggested in [Chart 44-15](#).
- Teach caregivers of patients with dementia to use validation therapy rather than reality orientation. Acknowledge the patient's feelings and concerns.
- Involve patients and families in developing a continuing plan of care to meet expected outcomes and maintain quality of life.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Adapt communication techniques for the patient with dementia as outlined in [Chart 44-13](#).

Physiological Integrity

- Assess for characteristic clinical manifestations in patients with classic migraine headaches as listed in [Chart 44-1](#).
- Recall that the pain of cluster headaches is usually accompanied by ipsilateral (same side) eye tearing, rhinorrhea, congestion, ptosis, facial sweating, eyelid edema, and/or miosis.
- Recognize that generalized seizures, such as the tonic-clonic seizure, involve both cerebral hemispheres. Partial seizures, also called *focal* or *local seizures*, usually involve only one hemisphere.
- During a seizure, document patient's body movements and other assessments as described in [Chart 44-6](#).
- Monitor for side and adverse effects of antiepileptic drugs (AEDs) as listed in [Chart 44-3](#).
- For patients who have had one or more seizures, place on "seizure precautions," which includes having oxygen and suctioning emergency equipment available, starting an IV access, and keeping the siderails up at all times. Indicate the reasons for the siderails to meet The Joint Commission requirements.
- Assess for clinical manifestations of meningitis as listed in [Chart 44-7](#).
- For patients with meningitis, carefully monitor neurologic status, including vital signs and neurovascular checks. Observe for signs and symptoms of increased intracranial pressure (ICP).
- Assess level of consciousness (LOC) as a priority in patients with encephalitis.
- Assess for key features of Parkinson disease as described in [Chart 44-10](#).
- Monitor for drug toxicity when patients are taking medications for Parkinson disease, especially levodopa combinations such as Sinemet. Delirium and decreased drug effectiveness are the most common indicators of toxicity.
- Keep in mind that newer surgical procedures, such as deep brain stimulation, and experimental stem cell therapies are becoming available as options to control symptoms of Parkinson disease.
- Assess cognitive and functional abilities of the patient with Alzheimer's disease, recognizing that it is a progressive dementia with several stages as listed in [Chart 44-12](#).
- Recall that Alzheimer's disease has a genetic predisposition.
- For patients with Alzheimer's disease, recall that the newer drugs seem to improve function and cognition (cholinesterase inhibitors, such as donepezil [Aricept]) or slow the disease process (Memantine) but they do not cure the disease.
- Administer psychotropic drugs to patients with Alzheimer's disease who also have mental/behavioral health problems, such as depression and severe agitation.
- Remember that Huntington disease is a chronic, hereditary illness that is transmitted as an autosomal dominant trait at the time of conception. Refer patients with the disease for genetic counseling.

Care of Patients with Problems of the Central Nervous System: The Spinal Cord

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Develop a teaching plan to educate the patient on ways to prevent back and neck pain, including the need for ergonomics in the workplace.
2. Prioritize the nursing care of the patient with a spinal cord injury (SCI).
3. Explain the importance of collaborating with the health care team when providing care for patients with SCI.
4. Plan how to integrate advance directives in the plan of care for patients with amyotrophic lateral sclerosis with respect to the patient's wishes.

Health Promotion and Maintenance

5. Identify community resources for patients with spinal cord health problems and their families.
6. In collaboration with the health care team, develop a discharge plan for the patient and family after a lumbar or cervical laminectomy.

Psychosocial Integrity

7. Describe the need to counsel patients with SCI and their partners on sexuality issues as needed.
8. Describe the impact of spinal cord health problems on patients and their families.

Physiological Integrity

9. Perform a comprehensive health assessment of the patient with a spinal cord injury.
10. Assess the patient with spinal cord health problems for mobility, gait, strength, and sensation.
11. Plan interventions to prevent complications of immobility when caring for the patient with spinal cord health problems.
12. Identify precautions to prevent injury when moving a patient with a spinal cord problem.
13. Apply knowledge of pathophysiology when caring for a patient having autonomic dysreflexia.
14. Explain the clinical manifestations and management options associated with spinal cord tumors.
15. Explain the pathophysiology of multiple sclerosis (MS) and amyotrophic lateral sclerosis (ALS).
16. Explain the role of drug therapy in managing patients with spinal cord problems.
17. Develop a postoperative plan of care for patients having spinal cord surgery, including monitoring for complications.

The spinal cord and its nerves play a major role in maintaining a person's needs for *mobility* and *sensation*. This chapter focuses on back pain, spinal cord injuries and tumors, and diseases that affect the spinal cord, such as multiple sclerosis (MS) and amyotrophic lateral sclerosis (ALS). These health

problems share a common characteristic of impaired *mobility* associated with decreased motor function. As a result, the patient's ability to perform ADLs is often affected. *Sensory* function also may be impaired, either temporarily or permanently. The spinal cord itself may be damaged, or the spinal

nerves leading from the cord to the extremities may be affected. In some cases, both the spinal cord and the nerves are involved.

BACK PAIN

Back pain is one of the most common reasons for visiting a health care provider. Disabling low back pain is the single greatest cause of injury in the working population. The lumbosacral (lower back) and cervical (neck) vertebrae are most commonly affected because these are the areas where the vertebral column is the most flexible. *Acute* back pain is usually self-limiting. If the pain continues for 3 months or if repeated episodes of pain occur, the patient has *chronic* back pain.

LUMBOSACRAL BACK PAIN (LOW BACK PAIN)

Pathophysiology

Lumbosacral back pain, referred to as **low back pain (LBP)**, is more common than cervical pain. Acute pain is caused by muscle strain or spasm, ligament sprain, disk (also spelled “disc”) degeneration (osteoarthritis), or herniation of the nucleus pulposus from the center of the disk. Herniated disks occur most often between the fourth and fifth lumbar vertebrae (L4-5) but may occur at other levels. A bulging or **herniated nucleus pulposus (HNP)** in the lumbosacral area can press on the adjacent spinal nerve (usually the sciatic nerve), causing severe burning or stabbing pain down into the leg or foot (Fig. 45-1). The specific area of pain depends on the level of herniation. Painful muscle spasms of the affected leg also may occur.

In addition to pain, numbness and tingling may be felt in the affected leg because spinal nerves have both motor and sensory fibers. The HNP may press on the spinal cord itself, causing leg weakness and bowel and bladder dysfunction. Sacral spinal nerves are part of the reflex system for the bowel and bladder. They also contain parasympathetic nerve fibers, which help control bowel and bladder function.

Back pain may also be caused by **spondylolysis**, a defect in one of the vertebrae usually in the lumbar spine. **Spondylolisthesis** occurs when one vertebra slips forward on the one below it, often as a result of spondylolysis. This problem causes pressure on the nerve roots, leading to pain in the

lower back and into the buttocks. Pain or numbness may also occur in the leg and foot. **Spinal stenosis**, a narrowing of the spinal canal, nerve root canals, or intervertebral foramina is typically seen in people older than 50 years. This narrowing may be caused by infection, trauma, herniated disk, and arthritis and disk degeneration. Most adults older than 50 years have some degree of degenerative disk disease although they may not be symptomatic.

Acute back pain usually results from injury or trauma. The patient typically hyperflexes or twists the back during a vehicular crash, or the injury occurs when the patient lifts a heavy object. Obesity places increased stress on the back muscles and can cause back pain. Smoking has been linked to disk degeneration, possibly caused by constriction of blood vessels that supply the spine. Congenital spinal conditions and scoliosis can also lead to back discomfort. Older adults are at high risk for both acute and chronic LBP. Petite, Euro-American women are at high risk for vertebral compression fractures from osteoporosis, which cause severe pain and decreased mobility. **Chart 45-1** provides a list of specific factors that can cause low back pain in the older adult. Vertebral compression fractures are discussed in detail in **Chapter 54**.

Health Promotion and Maintenance

Many of the problems related to acute back pain can be prevented by recognizing the cause of back pain and taking appropriate preventive measures. For example, good posture, proper lifting techniques, and exercise can significantly

CHART 45-1 NURSING FOCUS ON THE OLDER ADULT

Factors Contributing to Low Back Pain

- Changes in support structures
 - Spinal stenosis
 - Hypertrophy of the intraspinal ligaments
 - Osteoarthritis
 - Osteoporosis
- Changes in vertebral support and malalignment
 - Scoliosis
 - Lordosis
- Vascular changes
 - Diminished blood supply to the spinal cord or cauda equina caused by arteriosclerosis
 - Blood dyscrasias
 - Intervertebral disk degeneration

FIG. 45-1 Herniation of the nucleus pulposus.

decrease the incidence of low back pain. Nurses and other direct care staff members who move and lift patients are at a very high risk for LBP.

The U.S. Occupational Safety and Health Administration (OSHA) mandated that all industries develop and implement a plan to decrease musculoskeletal injuries among their workers. One way to meet this requirement is to develop an ergonomic plan for the workplace. **Ergonomics** is an applied science in which the workplace is designed to increase worker comfort (thus reducing injury) while increasing efficiency and productivity. An example is equipment design for office furniture that can help reduce back injuries. **Chart 45-2** summarizes various ways to help prevent LBP.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

The patient's primary concern is continuous pain. Some patients have so much pain that they walk in a stiff, flexed posture, or they may be unable to bend at all. They may walk with a limp, indicating possible sciatic nerve impairment. Walking on the heels or toes often causes severe pain in the affected leg, the back, or both.

Conduct a complete pain assessment as discussed in **Chapter 5**. Record the patient's current pain score, as well as the worst and best score since the pain began. Ask if pain occurs or gets worse at night or during rest. Determine if a recent injury to the back has occurred. It is not unusual for the patient to say "I just turned around and felt my back go out."

Inspect the patient's back for vertebral alignment and for tenderness and swelling caused by muscle spasm. Painful muscle spasms in the back and affected leg are common because the compressed nerve becomes inflamed and irritates nearby muscle tissue. Patients report stabbing, continuous pain in the muscle closest to the affected disk. They often describe a sharp, burning posterior thigh or calf pain that may radiate to the ankle or toes along the path of one or more spinal nerves. Pain usually does not extend the entire length

of the limb. Patients may also report the same type of pain in the middle of one buttock. The pain is often aggravated by sneezing, coughing, or straining. Driving a vehicle is particularly painful.

Ask whether **paresthesia** (tingling sensation) or numbness is present in the involved leg. Both extremities may be checked for sensation by using a pin or paper clip and a cotton ball for comparison of light and deep touch. The patient may feel sensation in both legs but may experience a stronger sensation on the unaffected side. Those with severe problems may lose both bowel and bladder control from sacral spinal nerve involvement.

If the sciatic nerve is compressed, severe pain occurs when the patient's leg is held straight and lifted upward. Foot, ankle, and leg weakness may accompany lower back pain. To complete the neurologic assessment, evaluate the patient's muscle tone and strength. Muscles in the extremity or lower back can atrophy as a result of severe chronic back pain. The patient has difficulty with movement, and certain movements create more pain than others.

Other information that may indicate more serious neurologic problems includes a history of fever and chills, recurrent skin or urinary tract infections, progressive motor and sensory loss, and difficulty with urination or having a bowel movement (due to involvement of sacral nerves). Patients older than 50 years and those with osteoporosis, immunosuppression, long-term use of steroids, or IV drug abuse require more thorough diagnostic studies.

Diagnostic Assessment

Imaging studies for patients who report mild nonspecific back pain may not be done depending on the nature of the pain. Patients with severe or progressive neurologic deficits or who are thought to have other underlying conditions (e.g., cancer, infection) require complete diagnostic assessment. X-rays of the spine are important to exclude fracture, spondylosis, or neoplasm as the causative agent. Flexion-extension views can be very useful to show instability of the spine. The imaging studies of choice are magnetic resonance imaging (MRI) or computerized tomography (CT) scanning. The MRI is usually the first test of choice because it is noninvasive. A CT myelogram is done when a better delineation of the bony anatomy and the specific nerve root involvement is needed. For patients having surgery, some physicians request a diskogram of the affected disk, especially when the level of the injury is not certain.

Electro-diagnostic testing, such as electromyography (EMG) and nerve-conduction studies, may help distinguish motor neuron diseases from peripheral neuropathies and **radiculopathies** (spinal nerve root involvement). These tests are especially useful in chronic diseases of the spinal cord or associated nerves. **Chapter 43** describes these tests in more detail.

INTERVENTIONS

Management of patients with back pain varies with the severity and chronicity of the problem. Most patients with acute LBP need only a short-term treatment regimen. The health care provider starts with conservative measures. If these are unsuccessful, surgery may be needed. Some patients have continuous or intermittent chronic pain that must be managed for an extended period, perhaps for their entire lives.

CHART 45-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Prevention of Low Back Pain and Injury

- Use proper body mechanics, with specific attention to bending, lifting, and sitting.
- Assess the need for assistance with your household chores or other activities.
- Participate in a regular exercise program, especially one that promotes back strengthening, such as swimming and walking.
- Do not wear high-heeled shoes.
- Use good posture when sitting, standing, and walking.
- Avoid prolonged sitting or standing. Use a footstool and ergonomic chairs and tables to lessen back strain. Be sure that equipment in the workplace is ergonomically designed to prevent injury.
- Keep weight within 10% of ideal body weight. Ensure adequate calcium intake.
- Stop smoking. If you are not able to stop, cut down on the number of cigarettes or decrease the use of other forms of tobacco.

Nonsurgical Management

Nonsurgical conservative management of LBP includes positioning, drug therapy, physical therapy, and weight control.

Acute Low Back Pain. The **Williams position** is typically more comfortable and therapeutic for the patient with LBP from a bulging or herniated disk. In this *position*, the patient lies in the semi-Fowler's position with a pillow under the knees to keep them flexed or sits in a recliner chair. This position relaxes the muscles of the lower back and relieves pressure on the spinal nerve root. Most patients also find that they need to change position frequently. Prolonged standing, sitting, or lying down increases back pain. If the patient must stand for a long time for work or other reason, shoe insoles or special floor pads may help decrease pain.

A firm mattress or a backboard placed under a soft mattress may provide back support for some patients. A flat position is sometimes helpful for the patient with a muscle injury. However, a flat position may aggravate the pain caused by disk trauma or disease.

The health care provider prescribes acetaminophen, muscle relaxants, and NSAIDs for acute LBP. Opioid analgesics are no more effective than nonsteroidal analgesics and should be avoided if at all possible. If they must be used, the course of therapy should be short to prevent adverse drug events. Short-term oral steroids in tapering doses may be prescribed for some patients to rapidly reduce inflammation.

Some patients may need an epidural injection for pain relief. A corticosteroid and an anesthetic are injected to reduce inflammation in the affected area. During a facet joint injection, fluoroscopy is used to insert a needle into the epidural space surrounding the facet and a corticosteroid is injected to coat the nerve roots and outside lining of the joints.

Chronic Low Back Pain. Patients having chronic low back pain may require an antiepileptic drug (AED) such as gabapentin (Neurontin) or oxcarbazepine (Trileptal) to treat neuropathic (chronic nerve) pain. The health care provider teaches the patient and/or family to start the patient on a low dose. The dose is gradually titrated until pain relief is achieved, the dose is not greater than the provider recommends, and the patient does not experience side effects. Patients should be monitored very carefully for symptoms of hyponatremia (low serum sodium), including generalized skeletal muscle weakness, headache, dizziness, and diarrhea. For older adults, observe for or teach family members to observe for falls due to dizziness and weakness, especially as the drug is increased.

For some patients, an AED is only partially effective for relieving back pain. The health care provider may add a tricyclic antidepressant, such as amitriptyline (Elavil, Levate 🍀) or desipramine (Norpramin, Pertofrane 🍀), to the drug regimen.

! NURSING SAFETY PRIORITY

Drug Alert

Teach older adults and their families to monitor for side and adverse effects of tricyclic antidepressants, including urinary retention (which can lead to infection), constipation, dry mouth, drowsiness, and acute confusion. Instruct them to notify their health care provider to report these changes, but do not stop these drugs abruptly.

Some patients with back pain may have temporary relief from *heat or cold* application. Heat increases blood flow to the affected area and promotes the healing of injured nerves.

Moist heat from heat packs or hot towels applied for 20 to 30 minutes at least four times per day is often recommended. Hot showers or baths may also be beneficial, although there is insufficient data to support the use of *superficial* heat/cold applications for low back pain (van Middelkoop et al., 2011).

The physical therapist (PT) may provide *deep* heat therapy, such as ultrasound treatments and diathermy. Some patients may receive **phonophoresis**, which is the application of a topical drug (e.g., lidocaine, hydrocortisone) followed by continuous ultrasound for 10 minutes. **Iontophoresis** is a similar procedure in which a small electrical current and dexamethasone are typically used. Both procedures push the medication into the subcutaneous tissue and provide longer-lasting pain relief.

The *physical therapist* also works with the patient to develop an individualized exercise program. The type of exercises prescribed depends on the location and nature of the injury and the type of pain. The patient does not begin exercises until acute pain is reduced by other means. Several specific exercises for LBP are listed in **Chart 45-3**. A systematic review of 37 studies showed that there is low quality evidence for the effectiveness of exercise for low back pain (van Middelkoop et al., 2011). Water therapy combined with exercise is helpful for some patients with chronic pain. The water also provides muscle resistance during exercise to prevent atrophy.

Weight control may help reduce chronic lower back pain by decreasing the strain on the vertebrae caused by excess weight. If the patient's weight exceeds the ideal by more than 10%, caloric restriction is recommended. Health care providers must be sensitive when reinforcing the need for patients to lose weight to prevent or to lessen chronic back pain. Positive reinforcement and self-esteem building are integral to the nutrition plan.

Complementary and Alternative Therapies. The patient may find that nontraditional and complementary therapies provide short-term pain relief. Patients with low back muscle injuries or mild nerve involvement may find relief of pain

CHART 45-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Typical Exercises for Chronic or Postoperative Low Back Pain

Extension Exercises

- **Stomach lying:** Lie face down with a pillow under your chest; lift legs straight up (alternate legs) (may not be tolerated).
- **Upper trunk extension:** Lie face down with your arms at your sides, and lift your head and neck.
- **Prone push-ups:** Lie face down on a mat and, keeping your body stiff, push up to extend your arms.

Flexion Exercises

- **Pelvic tilt:** Lying on your back with your knees bent, tighten your abdominal muscles to push your lower back against the mat.
- **Semi-sit-ups:** Lying on your back with your knees bent, raise your upper body at a 45-degree angle and hold this position for 5 to 10 seconds.
- **Knee to chest:** Lying on your back with your knees bent, tighten your abdominal muscles to push your lower back against the mat. Now bring one or both knees to your chest and hold this position for 5 to 10 seconds.

from chiropractic therapies. The purpose of spinal manipulative therapy (SMT) is to promote alignment and prevent or treat pressure on nerve roots.

Imagery, acupuncture, music therapy, and herbal medicines are examples of other possible pain relief therapies for acute and chronic pain. Rubinstein et al. (2010) conducted a systematic review of research on the effectiveness of complementary and alternative medicine for chronic back pain. They concluded that acupuncture and herbal therapies provide short-term pain relief but spinal manipulation was not as effective. Chapters 2 and 5 describe most of these modalities in detail.

Surgical Management

Surgery is usually performed if conservative measures fail to relieve back pain or if neurologic deficits continue to progress. An orthopedic surgeon and/or neurosurgeon perform these surgeries. Two major types of surgery are used depending on the severity and exact location of pain: minimally invasive surgery (MIS) and conventional open surgical procedures. MIS is not done if the disk is pressing into the spinal cord (central cord involvement).

Preoperative Care. Preoperative care for the patient preparing for lumbar surgery is similar to that for any patient undergoing surgery (see Chapter 16). Teach the patient about postoperative expectations, including:

- Techniques to get into and out of bed
- Turning and moving in bed
- Sensations, such as numbness and tingling, that may occur in the affected leg or in both legs
- Home care activities and restrictions

Many patients are discharged to home within 23 hours or the next day after surgery. Therefore, before surgery, teach family members or other caregiver how to assist the patient and what restrictions the patient must follow at home.

A bone graft is done if the patient has a *spinal fusion*. The surgeon explains from where the bone for grafting will be obtained. The patient's own bone is used whenever possible, but additional bone from a bone bank may be needed. The surgeon provides verbal and written information about the type and the source of bone for surgery. Be sure that the patient signs an informed consent form before surgery. While the bone graft heals, the patient may wear a back orthotic device for 4 to 6 weeks after surgery, but this is not common practice today. Provide information about the importance of wearing the brace as instructed during the healing process, how to take it off and put it on while maintaining spinal alignment, and how to clean it.

Operative Procedures. *Minimally invasive surgeries (MISs)* have the advantage of being associated with less muscle injury, decreased blood loss, and decreased postoperative pain. The primary advantage of these surgical procedures is a shortened hospital stay and the possibility of an ambulatory (same-day) procedure. Spinal cord and nerve complications are also less likely. Several specific procedures are commonly performed.

A local anesthetic is given for the *microscopic (or surgical) endoscopic disectomy (MED)* or *percutaneous endoscopic disectomy (PED)*. The surgeon uses x-ray fluoroscopy to insert an endoscope (arthroscope) next to the affected disk. A special cutting tool or laser probe is threaded through the cannula for removal or destruction of the *disk pieces* that are

compressing the nerve root. A newer procedure combines the PED with *laser thermolysis* to also shrink the herniated disk before removal. Inpatient hospitalization is not necessary for this procedure.

A *microdisectomy* involves microscopic surgery directly through a 1-inch incision. This procedure allows easier identification of anatomic structures, improved precision in removing small fragments, and decreased tissue trauma and pain.

Laser-assisted laparoscopic lumbar disectomy combines a laser with modified standard disk instruments inserted through the laparoscope using an umbilical ("belly button") incision. The procedure may be used to treat herniated disks that are bulging but do not involve the vertebral canal. The primary risks of this surgery are infection and nerve root injury. The patient is typically discharged in 23 hours but may go home sooner.

The most common *conventional open procedures* are disectomy, laminectomy, and spinal fusion. These procedures involve a surgical incision to expose anatomic landmarks for extensive muscle and soft-tissue dissection. Major complications include nerve injuries, **diskitis** (disk inflammation), and dural tears (tears in the dura covering the spinal cord).

As the name implies, a *disectomy* is removal of a herniated disk. A *laminectomy* involves removal of part of the laminae and facet joints to obtain access to the disk space. When repeated laminectomies are performed or the spine is unstable, the surgeon may perform a **spinal fusion (arthrodesis)** to stabilize the affected area. Chips of bone are removed, typically from the iliac crest, or obtained from donor bone and are grafted between the vertebrae for support and to strengthen the back. Metal implants (usually titanium pins, screws, plates, or rods) may be required to ensure the fusion of the spine. Before closing, the surgeon may give an **intrathecal** (spinal) or epidural dose of long-acting morphine (Duramorph) to decrease postoperative pain.

Interbody cage fusion is a newer spinal implant. A cage-like device is implanted into the space where the disk was removed. Bone graft tissue is packed around the device. As with instrumentation and fusion, the bone graft grows into and around the cage and creates a stable spine at that level.

An adjunct for patients for whom fusion may be difficult is the placement of an implantable **direct current stimulation (DCS)** device to promote bone fusion. External bone stimulators may also be effective for healing bone fusions.

Postoperative Care. Postoperative care depends on the type of surgery that was performed. In the postanesthesia care unit (PACU), vital signs and level of consciousness are monitored frequently, the same as for any surgery. Best practices for PACU nursing care are discussed in Chapter 18.

Minimally Invasive Surgery. Patients go home the same day or the day after surgery with a Band-Aid or Steri-Strips over their small incision. Those having a microdisectomy may also have a clear or gauze dressing over the bandage. Most patients notice less pain immediately after surgery, but mild oral analgesics are needed for pain control while nerve tissue heals over the next few weeks. In collaboration with the health care provider and physical therapist, teach the patient to follow the prescribed exercise program, which begins immediately after discharge. Patients should start walking routinely every day. Complications of MIS are rare.

CHART 45-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing and Managing the Patient with Major Complications of Lumbar Spinal Surgery

COMPLICATION	ASSESSMENT/INTERVENTIONS
Cerebrospinal fluid (CSF) leakage	Observe for clear fluid on or around the dressing. If leakage occurs, place patient flat. Report CSF leakage immediately to the surgeon. (The patient is usually kept on flat bedrest for several days while the dural tear heals.)
Fluid volume deficit	Monitor intake and output; monitor drain output, which should not be more than 250 mL in 8 hr during the first 24 hr. Monitor vital signs carefully for hypotension and tachycardia.
Acute urinary retention	Assist the patient to the bathroom or a bedside commode as soon as possible postoperatively. Assist male patients to stand at the bedside as soon as possible postoperatively.
Paralytic ileus	Monitor for flatus or stool. Assess for abdominal distention, nausea, and vomiting.
Fat embolism syndrome (FES) (more common in people with spinal fusion)	Observe for and report chest pain, dyspnea, anxiety, and mental status changes (particularly common in older adults). Note petechiae around the neck, upper chest, buccal membrane, and conjunctiva. Monitor arterial blood gas values for decreased PaO ₂ .
Persistent or progressive lumbar radiculopathy (nerve root pain)	Report pain not responsive to opioids. Document the location and nature of pain. Administer analgesics as prescribed.
Infection (e.g., wound, diskitis, hematoma)	Monitor the patient's temperature carefully (a slight elevation is normal). Increased temperature elevation or a spike after the second postoperative day is possibly indicative of infection. Report increased pain or swelling at the wound site or in the legs. Give antibiotics as prescribed if infection is confirmed. Use clean technique for dressing changes.

Conventional Open Surgery. Early postoperative nursing care focuses on preventing and assessing complications that might occur in the first 24 to 48 hours (Chart 45-4). As for any patient undergoing surgery, take vital signs at least every 4 hours during the first 24 hours to assess for fever and for hypotension, which could indicate bleeding or severe pain. Perform a neurologic assessment every 4 hours. Of particular importance are movement, strength, and sensation in the extremities.

Carefully check the patient's ability to void. Pain and a flat position in bed make voiding difficult, especially for men. An inability to void may indicate damage to the sacral spinal nerves, which control the detrusor muscle in the bladder. Opioid analgesics have also been associated with difficulty voiding. The patient with a disectomy or laminectomy

typically gets out of bed with assistance on the evening of surgery, which may help with voiding.

Pain control may be achieved with patient-controlled analgesia (PCA) with morphine. The route is changed to oral administration after the patient is able to take fluids or the next morning.

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient after back surgery, inspect the surgical dressing for blood or any other type of drainage. Clear drainage may mean cerebrospinal fluid (CSF) leakage. The loss of a large amount of fluid may cause the patient to report having a sudden headache. Report signs of any drainage to the surgeon immediately. Bulging at the incision site may be due to a CSF leak or a hematoma, both of which should also be reported to the surgeon.

Empty the surgical drain, usually a Jackson-Pratt or Hemovac, and record the amount of drainage every 8 hours. The surgeon usually removes the drain in 24 to 36 hours.

Correct turning of the patient in bed is especially important. Teach the patient to log roll every 2 hours from side to back and vice versa. In **log rolling**, the patient turns as a unit while his or her back is kept as straight as possible. A turning sheet may be used for obese patients. Either turning method may require additional assistance, depending on how much the patient can assist and on his or her weight. Instruct the patient to keep his or her back straight when getting out of bed. He or she should sit in a straight-back chair with the feet resting comfortably on the floor.

Teach the patient to deep breathe every 2 hours to prevent atelectasis (alveolar collapse) and pneumonia. Until the patient can ambulate independently, he or she wears graduated compression stockings, sequential compression devices (SCDs), or pneumatic compression boots (PCBs) to prevent deep vein thrombosis (DVT) and possible pulmonary emboli. *Older adults are especially likely to develop these complications of immobility.*

When a spinal fusion is performed in addition to a laminectomy, more care is taken with mobility and positioning. The nurse or unlicensed assistive personnel (UAP) assist with log rolling the patient every 2 hours. For the conventional fusion, inspect both the iliac and spinal incision dressings for drainage and make sure they are intact. Remind the patient to avoid prolonged sitting or standing.

Community-Based Care

The patient with back pain who does not undergo surgery is typically managed at home. If back surgery is performed, the patient is usually discharged to home with support from family or significant others. For older adults without a community support system, a short-term stay in a nursing home or transitional care unit may be needed. Collaborate with the case manager or discharge planner, patient, and family to determine the most appropriate placement.

Home Care Management

Inform the patient and family members or significant other that the patient should have a firm mattress to provide support for the entire vertebral column. A bed board or large piece of plywood placed under a soft mattress may suffice. After *conventional open back surgery*, the patient may be limited in the number of times he or she is allowed to climb

CHART 45-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Use of Proper Body Positioning to Prevent Back Injury After Surgery

- When lifting an object, keep your back straight and do not bend at the waist; lift with your large thigh muscles.
- Avoid lifting heavy objects, such as furniture.
- Push objects rather than pull them.
- Do not twist your back.
- Avoid prolonged sitting or standing. Use a footstool to lessen back strain.
- Sit in chairs with good support. Sleep on a firm mattress.
- Avoid shoulder stooping; maintain proper posture.
- Do not walk or stand in high-heeled shoes for prolonged periods (for women).

stairs each day. However, daily walking is encouraged. The patient can usually return to work in 4 to 6 weeks, depending on the nature of the job and the extent and type of surgery. Some patients may not return for 3 to 6 months if their jobs are physically strenuous. Weight that may be lifted is initially limited to 5 pounds. The amount is gradually increased as healing occurs. Driving is not permitted for several weeks until the surgeon re-evaluates the patient.

Patients having any of the MIS procedures may resume normal activities within a few days up to 3 weeks after surgery, depending on the specific procedure that was done and the condition of the patient. He or she may take a shower on the third or fourth day after surgery. Teach the patient to remove the outer clear or gauze dressing, if any is in place, but leave the Steri-Strips in place for removal by the surgeon or until they fall off. Instruct the patient to contact the surgeon immediately if clear drainage seeps from the incision. Clear drainage usually indicates a meningeal tear and cerebrospinal fluid is leaking.

Teaching for Self-Management

The patient with an acute episode of back pain typically returns to his or her usual activities but may fear a recurrence. Remind the patient that he or she may never have another episode if caution is used. However, continuous or repeated pain can be frustrating and tiring. Encourage the patient and family members to plan short-term outcomes and take steps toward recovering slowly.

After surgery, in collaboration with the physical therapist, instruct the patient to:

- Continue with a weight-reduction diet, if needed.
- Stop smoking, if applicable.
- Use moist heat as needed.
- Perform strengthening exercises as instructed.

The physical therapist reviews and demonstrates the principles of body mechanics and muscle-strengthening exercises. The patient is then asked to demonstrate these principles (Chart 45-5). Formal physical therapy usually begins about 2 weeks after surgery. Teach the patient the importance of keeping all appointments and following the prescribed exercise plan.

The health care provider may want the patient to continue taking anti-inflammatory drugs and muscle relaxants. Remind the patient and family about the possible side effects of drugs and what to do if they occur.

In a few patients, back surgery is not successful. This situation, referred to as **failed back surgery syndrome (FBSS)**, is a complex combination of organic, psychological, and socioeconomic factors. Repeated surgical procedures often discourage these patients, who must continue pain management after multiple operations. Nerve blocks, implantable neurostimulators, and other chronic pain management modalities may be needed on a long-term basis.

! NURSING SAFETY PRIORITY

Critical Rescue

For patients who have a neurostimulator implanted in the epidural space, assess neurologic status below the level of insertion frequently. Monitor for early changes in sensation, movement, and muscle strength. Ensure that the patient can void without difficulty. *If any changes occur, document and report them immediately to the surgeon!*

Ziconotide (Prialt) is a drug used for severe chronic back pain and FBSS and is given by intrathecal (spinal) infusion with a surgically implanted pump. It is the first available drug in a new class called *N-type calcium channel blockers (NCCBs)*. NCCBs seem to selectively block calcium channels on those nerves that usually transmit pain signals to the brain. Ziconotide is also used for patients with cancer, acquired immune deficiency syndrome (AIDS), and unremitting pain from other nervous system disorders.

! NURSING SAFETY PRIORITY

Drug Alert

Ziconotide can be given with opioid analgesics but should *not* be given to patients with severe mental health/behavioral health problems because it can cause psychosis. *If symptoms such as hallucinations and delusions occur, teach patients to stop the drug immediately and notify their health care provider.*

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

When providing discharge teaching to a client after a lumbar laminectomy, the nurse teaches him or her to call the surgeon immediately for which potential complication?

- Discomfort at the incision site
- Decreased appetite in the morning
- Slight redness and itching at the incision site
- Clear drainage from the incision site

Health Care Resources

Assist the patient in identifying support systems (e.g., family, church groups, clubs) after back surgery or FBSS. For example, a spouse may help the patient with exercises or perform the exercises with the patient. Members of a church group may help run errands and do household chores.

The patient with back pain may continue physical therapy on an ambulatory basis after discharge. For unresolved pain, the patient may be referred to pain specialists or clinics, which are usually found in large metropolitan hospitals. A case manager may be assigned to the patient to help with resource management and utilization.

CERVICAL NECK PAIN

Pathophysiology

Cervical neck pain most often results from a bulging or herniation of the nucleus pulposus (HNP) in an intervertebral disk. As seen in Fig. 45-1, the disk tends to herniate laterally where the annulus fibrosus is weakest and the posterior longitudinal ligament is thinned. The result is spinal nerve root compression with resulting motor and sensory manifestations, typically in the neck, upper back (over the shoulder), and down the affected arm. The disk between the fifth and sixth cervical vertebrae (C5-6) is affected most often.

If the disk does not herniate, nerve compression may be caused by osteophyte (bony spur) formation from osteoarthritis. The osteophyte presses on the intervertebral foramen, which results in a narrowing of the disk and pressure on the nerve root. As with sciatic nerve compression, the patient with cervical nerve compression may have either continuous or intermittent chronic pain. When the disk herniates centrally, pressure on the spinal cord occurs.

Cervical pain—acute or chronic—may also occur from muscle strain, ligament sprain resulting from aging, poor posture, lifting, tumor, rheumatoid arthritis, osteoarthritis, or infection. The typical history of the patient includes a report of pain when moving the neck, which radiates to the shoulder and down the arm. The pain may interrupt sleep and may be accompanied by a headache or numbness and tingling in the affected arm. To determine the exact cause of the pain, a number of diagnostic tests may be used, including:

- Plain x-rays (show general arthritis changes and bony alignment)
- Computerized tomography (CT) scan (shows spinal bones, nerves, disks, and ligaments)
- Magnetic resonance imaging (MRI) (provides images of the spinal tissue, bones, spinal cord, nerves, ligaments, musculature, and disks)
- Bone scan (shows bone changes by injecting radioactive tracers, which attach to areas of increased bone production or show increased vascularity associated with tumor or infection)
- Myelogram/post-myelogram CT (evaluates nerve root lesions and any other mass lesion or infection that is within or impinging on the thecal sac)
- Electromyography/nerve conduction studies (helps differentiate cervical radiculopathy, ulnar or radial neuropathy, carpal tunnel syndrome, or other peripheral nerve problems)

PATIENT-CENTERED COLLABORATIVE CARE

Conservative treatment for acute neck pain is the same as described for low back pain except the exercises focus on the shoulders and neck. The physical therapist teaches the patient the correct techniques for performing “shoulder shrug,” “shoulder squeeze,” and “seated rowing.” If these treatments do not work, some health care providers prescribe a soft collar to stabilize the neck, especially at night. Using the collar longer than 10 days leads to increased pain and decreased muscle strength and range of motion. For that reason, some health care providers do not recommend collars for cervical disk problems.

CHART 45-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Care of the Patient After an Anterior Cervical Discectomy and Fusion

Postoperative Interventions

- Assess **a**irway, **b**reathing, and **c**irculation (ABCs) (first priority!).
- Check for bleeding and drainage at the incision site.
- Monitor vital signs and neurologic status frequently.
- Check for swallowing ability.
- Monitor intake and output.
- Assess the patient's ability to void (may be a problem secondary to opiates).
- Manage pain adequately.
- Assist the patient with ambulation within a few hours of surgery, if he or she is able.

Discharge Teaching

- Be sure that someone stays with the patient for the first few days after surgery.
- Review drug therapy.
- Teach care of the incision.
- Review activity restrictions:
 - No lifting
 - No driving until physician permission
 - No strenuous activities
- Walk every day.
- Call the surgeon if symptoms of pain, numbness, and tingling worsen or if swallowing becomes difficult.
- Wear brace or collar per surgeon's prescription

If conservative treatment is ineffective, surgery may be required, most often using a *conventional open surgical approach*. A neurosurgeon usually performs this surgery because of the complexity of the nerves and other structures in that area of the spine. Depending on the cause and the location of the herniation, either an anterior or posterior approach is used. An anterior cervical discectomy and fusion (ACDF) is commonly performed. The patient is fitted with a large neck brace before surgery. Routine preoperative and postoperative care is the same as described in [Chapters 16 and 18](#).

! NURSING SAFETY PRIORITY

Critical Rescue

The priority for care in the immediate postoperative period after an ACDF is maintaining an airway and ensuring that the patient has no problem with breathing. Swelling from the surgery can narrow the trachea, causing a partial obstruction.

[Chart 45-6](#) summarizes best practices for postoperative care and discharge planning. Complications of ACDF can occur from the brace or the surgery itself. The initial brace is worn for 4 to 6 weeks, depending on the patient. When it is removed, a soft collar is worn for several more weeks, or longer if needed. Potential complications of the anterior surgical approach can be found in [Chart 45-7](#).

Some patients may be candidates for minimally invasive surgery (MIS), such as percutaneous cervical discectomy through an endoscope, with or without laser thermolysis to shrink the herniated portion of the disk. The care for these patients is very similar to that for the patient with low back pain who has MIS (see discussion of surgical management of patients with low back pain on p. 963).

CHART 45-7 KEY FEATURES

Postoperative Complications of Anterior Cervical Discectomy and Fusion

- Hoarseness due to laryngeal injury; may be temporary or permanent
- Temporary dysphagia; may last few days to several months; usually not severe
- Esophageal, tracheal, or vertebral artery injury
- Wound infection
- Injury to the spinal cord or nerve roots
- Dura mater tears with associated cerebrospinal fluid leaks
- Pseudoarthrosis caused by nonunion of fusion
- Graft and screw loosening if a fusion was performed

SPINAL CORD INJURY

Medical-surgical nurses do not usually care for a patient with an *acute* spinal cord injury (SCI). However, a patient may be admitted to a medical-surgical unit for complication of the injury or other medical conditions. Caring for a patient with an SCI requires a patient-centered collaborative approach and involves nearly every health care team member to help meet the patient's expected outcomes.

Despite increased awareness and newer treatments for SCI, the effects of spinal trauma cannot be reversed. However, research continues to find ways to decrease the devastating effects of paralysis. A combination approach of cell transplant, growth of new neurons, drug therapy, and surgery may be the key to restoring some if not all of the patient's lost motor and sensory function.

Pathophysiology

Loss of motor function (*mobility*), *sensation*, reflex activity, and bowel and bladder control often result from an SCI. In addition, the patient may experience significant behavior and emotional problems as a result of changes in body image, role performance, and self-concept.

The SCIs are classified as complete or incomplete. A **complete spinal cord injury** is one in which the spinal cord has been severed or damaged in a way that eliminates all innervation below the level of the injury. Injuries that allow some function or movement below the level of the injury are described as an **incomplete spinal cord injury**. Incomplete injuries are more common than complete SCIs.

Mechanisms of Injury

When enough force is applied to the spinal cord, the resulting damage causes many neurologic deficits. Sources of force include direct injury to the vertebral column (fracture, dislocation, and subluxation [partial dislocation]) or penetrating trauma from violence (gunshot or knife wounds). Although in some cases the cord itself may remain intact, at other times the cord undergoes a destructive process caused by a contusion (bruise), compression, laceration, or transection (severing of the cord, either complete or incomplete) (Nayduch, 2010).

The causes of SCI can be divided into primary and secondary mechanisms of injury. Four *primary* mechanisms may result in an SCI:

- Hyperflexion
- Hyperextension

FIG. 45-2 Hyperflexion injury of the cervical spine.

- Axial loading, or vertical compression
- Excessive rotation

Penetrating injuries to the cord may also occur.

A **hyperflexion** injury occurs when the head is suddenly and forcefully accelerated (moved) forward, causing extreme flexion of the neck (Fig. 45-2). This type of injury often occurs in head-on vehicle collisions and diving accidents. Flexion injury to the lower thoracic and lumbar spine may occur when the trunk is suddenly flexed on itself, such as occurs in a fall on the buttocks. The posterior ligaments can be stretched or torn, or the vertebrae may fracture or dislocate. Either process may damage the spinal cord, causing hemorrhage, edema, and necrosis.

Hyperextension injuries occur most often in vehicle collisions in which the vehicle is struck from behind or during falls when the patient's chin is struck (Fig. 45-3). The head is suddenly accelerated and then decelerated. This stretches or tears the anterior longitudinal ligament, fractures or subluxates the vertebrae, and perhaps ruptures an intervertebral disk. As with flexion injuries, the spinal cord may easily be damaged.

Diving accidents, falls on the buttocks, or a jump in which a person lands on the feet can cause many of the injuries attributable to **axial loading** (vertical compression) (Fig. 45-4). A blow to the top of the head can cause the vertebrae to shatter. Pieces of bone enter the spinal canal and damage the cord. **Rotation** injuries are caused by turning the head beyond the normal range.

Penetrating injuries to the spinal cord are classified by the speed of the object (e.g., knife, bullet) causing the injury. Low-speed or low-impact injuries cause damage directly at the site or local damage to the spinal cord or spinal nerves. In contrast, high-speed injuries that occur from gunshot wounds cause both direct and indirect damage.

FIG. 45-3 Hyperextension injury of the cervical spine.

Secondary injury worsens the primary injury. Secondary injuries include:

- Hemorrhage
- Ischemia (lack of blood flow)
- Hypovolemia (decreased circulating blood volume)
- Neurogenic shock (a *medical emergency*)

The spinal cord may be contused, lacerated, or compressed by the injury. Petechial hemorrhage into the central gray matter and later into the white matter may result. Edema occurs when the cord is compressed by hemorrhage or bony fragments. Hemorrhage and loss of blood vessel tone (dilation) after *severe* cord injury may result in hypovolemia. In some patients, especially those with cervical spine injury, a type of hypovolemic shock called *neurogenic shock* may occur (McCance et al., 2010).

Etiology

Trauma is the leading cause of spinal cord injuries (SCIs); almost half result from motor vehicle crashes. The second leading cause is falls, followed by acts of violence (usually gunshot wounds [GSWs]) and recreational sports accidents (National Spinal Cord Injury Statistical Center, 2010). Falls are particularly likely among older adults. Spinal cord damage in adults can also result from diseases such as benign or malignant tumors.

Incidence/Prevalence

According to the National Spinal Cord Injury Statistical Center (2010), approximately 12,000 new SCIs occur every year in the United States. Almost 81% of all SCIs occur in

FIG. 45-4 Axial loading (vertical compression) injury of the cervical spine and the lumbar spine.

young males, with the majority being Euro-American. Cervical cord injuries are more common than thoracic or lumbar cord injuries.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

When obtaining a history from a patient with an SCI, gather as much data as possible about how the accident occurred and the probable mechanism of injury. Questions include the location and position of the patient immediately after the injury, the symptoms that occurred after the injury, and the changes that have occurred since the initial signs and symptoms. If possible, ask prehospital rescue personnel about the type of immobilization devices used and whether any problems occurred during stabilization and transport to the hospital. Review the patient's medical record regarding the treatment given at the scene of injury or in the emergency department (ED) (e.g., drugs, IV fluids). Communicate with the ED nurse as he or she "hands off" the patient. Use the **s**ituation, **b**ackground, **a**ssessment, **r**ecommendation (SBAR) communication technique to collect valuable information for continuing patient care (per The Joint Commission's National Patient Safety Goals). (See Chapter 1 for how to use SBAR.)

Obtain the patient's medical history, including a history of arthritis of the spine, congenital deformities, osteoporosis or osteomyelitis, cancer, and previous injury or surgery of the neck or back. These health problems may cause or contribute to an SCI. A detailed history of any respiratory problems is

particularly important if the patient has experienced a cervical SCI.

Physical Assessment/Clinical Manifestations

Initial Assessment. Assessing the ABCs (airway, breathing, circulation) is the priority for any trauma patient. *Therefore the first priority for the patient with an SCI is to assess the patient's airway, breathing pattern, and circulation status.* The airway may be compromised because of foreign body obstruction from the tongue or teeth due to facial trauma, injury to the larynx, or mandibular (jaw) fracture. After an airway is established, assess the patient's breathing pattern. The patient with a cervical SCI is at high risk for respiratory compromise because the cervical spinal nerves (C3-5) innervate the phrenic nerve, which controls the diaphragm. A significant head injury, pneumothorax (air in the chest cavity), hemothorax (blood in the chest cavity), and/or fractured ribs may also cause respiratory distress. Injuries to the occiput (back of the head) and C2 are more likely to occur in the older adult who fell from a low height. Endotracheal intubation with mechanical ventilation may be necessary to prevent respiratory arrest.

Assess for indications of intra-abdominal hemorrhage or hemorrhage or bleeding around fracture sites. Indicators of hemorrhage include hypotension and tachycardia with a weak and thready pulse.

Use the Glasgow Coma Scale (see Chapter 43) or other agency-approved assessment tool to assess the patient's level of consciousness (LOC). Cognitive impairment as a result of an associated traumatic brain injury (TBI) or substance abuse is common in patients with traumatic SCIs. Perform a detailed assessment of the patient's motor and sensory status to assist in determining the level of injury and serve as baseline data for future comparison. The level of injury is the lowest neurologic segment with intact or normal motor and sensory function. **Tetraplegia** (also called *quadriplegia*) (paralysis) and **quadripareisis** (weakness) involve all four extremities, as seen with cervical cord and upper thoracic injury. **Paraplegia** (paralysis) and **paraparesis** (weakness) involve only the lower extremities, as seen in lower thoracic and lumbosacral injuries or lesions.

Spinal shock, also called **spinal shock syndrome**, occurs immediately as the cord's response to the injury. The patient has complete but temporary loss of motor, sensory, reflex, and autonomic function that often lasts less than 48 hours but may continue for several weeks (McCance et al., 2010). Muscle spasticity, reflex activity, and bladder function begin in patients with cervical or high thoracic injuries when spinal shock is resolved.

Sensory and Motor Assessment. With a complete SCI, changes below the level of the injury include:

- Absence of tactile sensation
- Flaccid paralysis (inability to move) of all voluntary muscles

Sensation is carried from the peripheral nerves to the spinal cord and up to the cerebral cortex through several specific tracts. Injury to the spinal cord may prevent those impulses from reaching the brain. To test sensory abilities, ask the patient to close his or her eyes. Touch the skin with a clean safety pin or cotton-tipped applicator, and ask whether he or she can feel the pinprick or light touch. Compare bilateral responses. Follow the sensory distribution of the skin

dermatomes (see Fig. 43-5 in Chapter 43), with the examination beginning in the area of reported loss of sensation and ending where sensation becomes normal. For example, sensation of the top of the foot and calf of the leg is spinal skin segment (dermatome) levels L3, L4, and L5. The area at the level of the umbilicus is T10, the clavicle (collarbone) is C3 or C4, and finger sensation is C7 and C8. The patient may report a complete sensory loss, **hypoesthesia** (decreased sensation), or **hyperesthesia** (increased sensation).

In addition to performing a routine motor evaluation of the patient, selected muscles are tested in a more systematic fashion (Chart 45-8). Many scales are available to measure motor function. The American Spinal Injury Association (ASIA) recommends a six-point grading scale, with 0 being no movement and 5 being normal strength against full resistance (see Table 52-2 in Chapter 52). Ask the patient to flex and extend the elbows, elevate both arms off the bed, flex and extend the wrists and fingers, and touch each finger to the thumb. Patients with spinal injuries at the fifth or sixth cervical vertebra often can flex but not extend their arms. Observe the patient's ability to move the lower extremities. Ask him or her to wiggle the toes, flex and extend the feet and knees, and move one or both hips.

The advanced practice nurse or health care provider may also test deep tendon reflexes (DTRs), including the biceps (C5), triceps (C7), patella (L3), and ankle (S1). It is not unusual for these reflexes, as well as all movement or sensation, to be absent immediately after the injury because of spinal shock. After shock has resolved, the reflexes may return if the lesion is incomplete or involves upper motor neurons.

Cardiovascular and Respiratory Assessment. Cardiovascular dysfunction results from disruption of sympathetic fibers of the autonomic nervous system (ANS), especially if the injury is above the sixth thoracic vertebra. Bradycardia, hypotension, and hypothermia occur because of loss of sympathetic input. These changes may lead to cardiac dysrhythmias. *A systolic blood pressure below 90 mm Hg requires treatment because lack of perfusion to the spinal cord could worsen the patient's condition.* In addition, the lack of sympathetic or hypothalamic control causes the patient to lose thermoregulatory functions. As a result, the body tends to assume

CHART 45-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing Motor Function in the Patient with a Spinal Cord Injury

- To assess C4-5, apply downward pressure while the patient shrugs his or her shoulders upward.
- To assess C5-6, apply resistance while the patient pulls up his or her arms.
- To assess C7, apply resistance while the patient straightens his or her flexed arms.
- To assess C8, make sure the patient is able to grasp an object and form a fist.
- To assess L2-4, apply resistance while the patient lifts his or her legs from the bed.
- To assess L5, apply resistance while the patient dorsiflexes his or her feet.
- To assess S1, apply resistance while the patient plantar flexes his or her feet.

the temperature of the environment and attempts to compensate by increasing extracellular fluid.

A patient with a cervical SCI is at risk for *breathing* problems resulting from an interruption of spinal innervation to the respiratory muscles. In collaboration with the respiratory therapist (RT), if available, perform a complete respiratory assessment, including pulse oximetry for arterial oxygen saturation. The RT should also evaluate vital capacity and minute volume as part of the assessment. These tests are repeated as the patient's clinical status requires. Assess for respiratory complications such as atelectasis and pneumonia.

Gastrointestinal and Genitourinary Assessment. Assess the patient's *abdomen* for manifestations of internal bleeding, distention, or paralytic ileus. Hemorrhage may result from the trauma, or it may occur later from a stress ulcer or the administration of steroids. Monitor for abdominal pain and changes in bowel sounds. Paralytic ileus may develop within 72 hours of hospital admission. During the period of spinal shock, peristalsis decreases, leading to a loss of bowel sounds and gastric distention. This lack of or interference with autonomic innervation may lead to a reflex or hypotonic bowel.

Autonomic dysfunction initially causes an areflexic (neurogenic) bladder (no reflex ability for bladder contraction), which later leads to urinary retention. The patient is at risk for urinary tract infection from an indwelling urinary catheter; intermittent catheterizations; or bladder distention, stasis, and/or overflow.

Assessment of Patients for Long-Term Complications. As patients learn to live with their spinal cord injuries, they usually experience many body changes and complications of prolonged immobility. For example, muscle wasting results from long-term flaccid paralysis in patients with **lower motor neuron (LMN)** lesions (usually lower thoracic or lumbosacral injuries). Incomplete lesions or **upper motor neuron (UMN)** lesions (usually cervical and upper thoracic injuries) cause muscle spasticity, which can lead to contractures of the joints.

For any spinal cord-injured patient, observe the condition of the patient's skin, especially over pressure points, at least twice daily. Assess any reddened area carefully, and monitor it daily for change. Turn patients frequently (every 1-2 hours) and use a pressure-reducing mattress or special bed to help prevent skin breakdown.

Another complication of prolonged immobility is **heterotopic ossification** (bony overgrowth, often into muscle). Assess for swelling, redness, warmth, and decreased range of motion (ROM) of the involved extremity. Changes in the bony structure are not visible until several weeks after initial symptoms appear.

Psychosocial Assessment

The patient with a complete spinal cord injury may be hospitalized for 3 months or longer, including acute care and rehabilitation. Life expectancy has increased, but it is still well below that of people without an SCI. The risk for death is significantly higher during the first year after injury than during subsequent years due to complications of impaired mobility.

If possible, obtain information about the patient's pre-injury psychosocial status and usual methods of coping with illness, difficult situations, and disappointments. Determine the patient's level of independence or dependence and his or her comfort level in discussing feelings and emotions with

family members or close friends. Patients who are emotionally secure and have a positive self-image, supportive family, and financial and job security often adapt best to their injury. Information about the patient's spiritual and religious beliefs or cultural background also assists the nurse in developing the plan of care. The patient with an SCI must cope with changes in body image, self-esteem, independence, role relationships, and sexuality.

In addition, assess family members or significant others to determine how well they are coping with the patient's injury and their role changes. Help prepare the patient and family for a possibility of extensive rehabilitation and changes in lifestyle. Financial constraints and concern about long-term care may cause additional stress.

Laboratory Assessment

The health care provider requests routine laboratory studies for the patient with an SCI to establish baseline data or to prepare for surgery. A urinalysis is used to check for the presence of blood in the urine after trauma. End-tidal carbon dioxide levels or arterial blood gas analysis is done to monitor the respiratory status of a patient at risk for respiratory insufficiency. The findings should be within normal limits unless the patient has a history of heavy smoking, pre-injury pulmonary disease, or respiratory failure. Respiratory failure is indicated by decreased oxygen levels, increased carbon dioxide levels, and respiratory acidosis.

Check laboratory values for a low hemoglobin count, leukocytosis (increased white blood cells [WBCs]), lymphocytopenia (decreased lymphocytes), and thrombocytopenia (decreased platelets), which can occur in patients with cervical spine injuries. These abnormalities may be related to lack of autonomic innervation to the hematopoietic (blood-cell producing) system. Observe patients for clinical signs and symptoms of these changes, such as an increased bleeding tendency.

Imaging Assessment

If available, spiral computed tomography (CT) or multi-slice CT is obtained as soon as possible, especially for the patient who has sustained multiple trauma. Otherwise, CT or magnetic resonance imaging (MRI) is performed to determine the degree and extent of damage to the spinal cord and to detect the presence of blood and bone within the spinal column. The health care provider requests a complete x-ray series of the spine to identify vertebral fractures, subluxation, or dislocation.

ANALYSIS

The priority problems for patients with a spinal cord injury (SCI) are:

1. Difficulty breathing related to upper motor neuron injury
2. Potential for neurogenic shock related to loss or interruption of sympathetic innervation in patients with SCIs above T6
3. Potential for further spinal cord injury related to swelling and/or fractures
4. Impaired Physical Mobility and/or Self-Care Deficit (the level depends on the extent and level of the injury) related to decreased or absent muscle control
5. Spastic or flaccid bladder and bowel related to direct neurologic damage or disruption in nerve impulses

6. Impaired adjustment related to disability requiring need for life change

PLANNING AND IMPLEMENTATION

The desired outcomes of patient-centered collaborative care are to stabilize the vertebral column as needed, manage damage to the spinal cord, and prevent secondary effects of injury. Many patients with previous spinal cord injuries (SCIs) are admitted to the acute care or long-term care setting for complications of immobility, such as pressure ulcers or septicemia resulting from pressure ulcers and fractures resulting from osteoporosis.

Managing the Airway and Improving Breathing

Planning: Expected Outcomes. The patient with an SCI is expected to have a patent airway and adequate ventilation.

Interventions. *Airway management is the priority for a patient with cervical spinal cord injury!* Patients with injuries at or above T6 are especially at risk for respiratory complications and pulmonary embolus during the first 5 days after injury. These complications are due to impaired functioning of the intercostal muscles and decreased mobility. Depending on the level of injury, intubation or tracheotomy with mechanical ventilation may be needed.

NURSING SAFETY PRIORITY

Action Alert

Assess breath sounds every 2 to 4 hours during the first few days after spinal cord injury, and document and report any adventitious or diminished sounds. Monitor vital signs carefully, and watch for changes in respiratory pattern.

Teach the patient who is tetraplegic to cough by placing his or her hands on either side of the rib cage or upper abdomen below the diaphragm. This technique is sometimes called “assisted coughing,” “quad cough,” or “cough assist.” As the patient exhales, push upward to help expand the lungs and cough.

Encourage the patient to use an incentive spirometer. The nurse and respiratory therapist perform a respiratory assessment at least every 8 hours to determine the effectiveness of these strategies. In some cases it may be necessary to perform oral or nasal suctioning if the patient cannot clear the airway of secretions effectively.

Closely monitor the patient for clinical manifestations of life-threatening respiratory complications, such as pneumonia, pulmonary emboli, and atelectasis. These problems decrease the life expectancy of SCI patients and have replaced renal failure as the leading cause of death.

Monitoring for Neurogenic Shock

Planning: Expected Outcomes. The patient is expected to not develop neurogenic shock. If signs and symptoms of this potentially life-threatening complication occur, the patient is expected to receive prompt intervention.

Interventions. Maintain adequate hydration through IV therapy and oral fluids as appropriate, depending on the patient’s overall condition. Carefully observe for manifestations of **neurogenic shock**, which may occur within 24 hours after injury most commonly in patients with injuries above T6. This potentially life-threatening problem results from

disruption in the communication pathways between upper motor neurons and lower motor neurons.

NURSING SAFETY PRIORITY

Critical Rescue

Monitor the patient with acute spinal cord injury at least hourly for:

- Severe bradycardia
- Warm, dry skin
- Severe hypotension

Notify the physician immediately if these symptoms occur, because this problem is an emergency! Neurogenic shock is treated symptomatically by restoring fluids to the circulating blood volume and providing supportive care to stabilize the patient.

Preventing Further Spinal Cord Injury

Planning: Expected Outcomes. The patient with an acute SCI is expected to demonstrate adequate spinal cord stabilization as evidenced by no further deterioration in neurologic status.

Interventions. If the patient has a fractured vertebra, the primary concern of the health care team is to reduce and immobilize the fracture to prevent further damage to the spinal cord from bone fragments. Nonsurgical techniques include external fixation or orthotic devices, but surgery is usually needed to stabilize the spine and prevent further spinal cord damage.

Assess the patient’s neurologic status, vital signs, pulse oximetry, and pain score at least every 1 to 4 hours depending on the patient’s overall condition. *Document your assessments carefully and in detail, particularly changes in motor or sensory function in the extremities. Failure to do so may prevent other staff members from quickly recognizing deterioration in neurologic status.*

Regardless of the level of SCI, keep the patient in proper body alignment to prevent further cord injury or irritability. Devices such as traction, orthoses, or collars may be used to keep the spine immobilized during healing and rehabilitation.

Spinal Immobilization and Stabilization. The patient may be placed in fixed skeletal traction to realign the vertebrae, facilitate bone healing, and prevent further injury, often after surgical stabilization. The most commonly used device for immobilization of the *cervical spine* is the halo fixation device, which is worn for 8 to 12 weeks. Cervical tongs are used less often today. Either device is inserted by the physician into the outer aspect of the skull. For patients not having surgery, the addition of traction helps reduce the fracture.

The **halo fixator** is a static traction device (Fig. 45-5). Four pins (or screws) are inserted into the skull. The metal halo ring may be attached to a plastic vest or cast when the spine is stable, allowing increased patient mobility.

NURSING SAFETY PRIORITY

Action Alert

Never move or turn the patient by holding or pulling on the halo device. Do not adjust the screws holding it in place. Check the patient’s skin frequently to ensure that the jacket is not causing pressure. Pressure is avoided if one finger can be inserted easily between the jacket and the patient’s skin. Monitor the patient’s neurologic status for changes in movement or decreased strength.

FIG. 45-5 Halo fixation device with jacket.

Common complications of the halo device are pin loosening, local infection, and scarring. More serious complications include osteomyelitis (cranial bone infection), subdural abscess, and instability. Hospital policy is followed for pin site care, which may specify the use of solutions such as saline. Vaseline dressings may also be used. *Monitor vital signs for indications of possible infection (e.g., fever, purulent drainage from the pin sites), and report any changes to the physician immediately.*

Nonsurgical treatment of *thoracic and lumbosacral injuries* is often challenging. Most health care providers choose to refer the patient for surgery and then immobilize the spine with lightweight, custom-fit thoracic lumbar sacral orthoses (TLSOs) to prevent prolonged periods of immobility.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client was admitted this morning with an incomplete spinal cord injury and is placed in a halo fixator vest after surgery. Which assessment finding will the nurse report immediately to the health care provider?

- A. Pulse rate of 78 beats/min
- B. Blood pressure of 88/42 mm Hg
- C. Pain level of 4 on a 0-to-10 pain scale
- D. Loosened halo vest

Drug Therapy. *Methylprednisolone (Solu-Medrol)* may be prescribed depending on physician preference and the condition of the patient. This drug decreases inflammation, such as that caused by injury to spinal cord and nerve tissue. Monitor the patient receiving IV methylprednisolone closely for adverse drug events, including infection, elevated serum glucose, and stress ulcers. *Dextran*, a plasma expander, may be used to increase capillary blood flow within the spinal cord and to prevent or treat hypotension. *Atropine sulfate* is used to treat bradycardia if the pulse rate falls below 50 to 60 beats

per minute. Hypotension, if severe, is treated with inotropic and sympathomimetic agents such as dopamine hydrochloride (Intropin) and isoproterenol.

Centrally acting skeletal muscular relaxants, such as tizanidine (Zanaflex, Sirdalud), may help control severe muscle spasticity (usually upper motor neuron [UMN] injuries). However, these drugs cause severe drowsiness and sedation in most patients and may not be effective in reducing spasticity. As an alternative to these drugs, *intrathecal baclofen (Lioresal) (ITB)* therapy may be prescribed. This drug is administered through a programmable, implantable infusion pump and intrathecal catheter directly into the cerebrospinal fluid. The pump is surgically placed in a subcutaneous pouch in the lower abdomen. Monitor for common adverse effects, which include sedation, fatigue, dizziness, and changes in mental status. *Seizures and hallucinations may occur if ITB is suddenly withdrawn.*

Other drugs to prevent or treat complications of immobilization may be needed *later* during the rehabilitative phase. For example, celecoxib (Celebrex) may be prescribed to prevent or treat **heterotopic ossification** (bony overgrowth). Calcium and bisphosphonates may prevent the osteoporosis that results from impaired mobility. Osteoporosis can cause fractures in later years. Early and continued exercise may help decrease the incidence of these complications. **Chapter 8** discusses complications of immobility and drug therapy in more detail.

Surgical Management. Emergency surgery may be indicated if there is evidence of spinal cord compression. The procedure is usually necessary to remove bone fragments, hematomas, or penetrating objects such as a bullet to prevent further spinal cord damage. A **decompressive laminectomy** (removal of one or more laminae) allows for cord expansion from edema if more conventional measures fail to prevent neurologic deterioration.

Additional surgical procedures to stabilize and support the spine may be performed at the discretion of the surgeon, depending on the patient's condition and the extent of the injury. Typical procedures include wiring and spinal fusion for cervical injuries and the insertion of steel or metal rods (e.g., Harrington rods) to stabilize thoracic and lumbar spinal injuries.

During a cervical fusion, the surgeon reduces the fracture by placing the bone ends in proper alignment. Metal wiring is then used to secure bone chips (bone graft) taken from the patient's hip. The patient wears a halo vest to immobilize the spine during the healing process.

For thoracic and lumbar fusions, metal or steel rods (e.g., Harrington rods) are used to keep the bone ends in alignment after fracture reduction. After surgery, the patient usually wears a TLSO to keep the operative area immobilized during recovery.

NURSING SAFETY PRIORITY

Action Alert

After surgical spinal fusion, assess the patient's neurologic status and vital signs at least every hour for the first 4 to 6 hours and then, if the patient is stable, every 4 hours. Assess for complications of surgery, such as hematoma and edema. Look for swelling under the skin.

A complete discussion of general postoperative nursing care is found in [Chapter 18](#). Spinal fusions were described earlier in this chapter on p. 964.

Managing Impaired Mobility and Self-Care Deficit

Planning: Expected Outcomes. *The patient with an SCI is expected to be free from complications of immobility and perform ADLs as independently as possible with or without assistive/adaptive devices.*

Interventions. The patient with an SCI is especially at risk for pressure ulcers, contractures, venous thromboembolism (deep vein thrombosis and/or pulmonary embolus), and fractures related to osteoporosis. Patients with high SCIs are also at risk for orthostatic hypotension. Proper positioning not only helps prevent complications but also provides alignment to prevent further spinal cord injury or irritability.

When sitting in a chair, the patient is repositioned or taught to reposition himself or herself more often than every hour. Paraplegic patients usually perform frequent “wheelchair push-ups” to relieve skin pressure. *Special pressure-relief devices such as gel pads or cyclic pressure-relief devices may be used in the wheelchair or the bed, but these tools do not eliminate the need for regular turning or repositioning.* [Chapter 8](#) discusses in detail the prevention of and nursing care for many complications associated with impaired physical mobility.

Patients with cervical cord injuries are especially at high risk for orthostatic (postural) hypotension, but anyone who is immobilized may have this problem. If the patient changes from a lying position to a sitting or standing position too quickly, he or she may experience hypotension, which could result in dizziness and falls. Because of interrupted sympathetic innervation caused by the spinal cord injury, the blood vessels do not constrict quickly enough to push blood up into the brain. This causes dizziness or light-headedness and possible falls with syncope (“blackout”).

The most important part of promoting self-management is setting realistic expected outcomes on the basis of the patient’s potential mobility and functional level. Even patients with a cervical SCI often learn how to perform most ADLs independently in specialized rehabilitation programs. See [Chapter 8](#) for a detailed discussion of interventions to promote mobility and ADLs.

Managing Urinary and Bowel Elimination

Planning: Expected Outcomes. The patient with an SCI is expected to achieve control of elimination of urine and stool without complications, if possible.

Interventions. Patients with SCIs have reflex or neurogenic loss of bowel and bladder control. Many can become continent if they rigorously adhere to an established program. The type of program depends on the usual elimination pattern and whether the injury involved upper motor neurons (UMNs) or lower motor neurons (LMNs). A urologic evaluation may be needed to identify bladder type.

Patients with injuries to the lumbosacral area usually have an LMN (flaccid) bladder and bowel. Patients with **flaccid bladders** may achieve emptying of the bladder by performing a Valsalva maneuver or tightening the abdominal muscles. These techniques are not successful for all LMN injuries. To determine the effectiveness of these maneuvers, use a bedside

bladder ultrasound device to measure bladder residual. This use of this device is discussed in [Chapter 69](#).

Some patients rely solely on intermittent catheterization two or three times daily to empty the bladder. Obese patients and those with very-high-level SCIs may need an indwelling urinary catheter for a period of time. External urinary catheters connected to a leg bag may be used for men.

The patient with *any* SCI is at risk for long-term renal complications, such as hydronephrosis, renal failure, and kidney stones. Urinary tract infections (UTIs) are common because organisms are introduced into the urinary tract by urinary catheters. Patients with an SCI may not be aware of the infection because they cannot feel dysuria, urgency, or back pain. They must rely on other signs and symptoms, such as foul-smelling urine or fever.

Teach the patient that the essential elements of a bowel program include stool softeners, increased fluid intake (unless medically contraindicated), high-fiber diet, and a consistent time for elimination. *Rectal digital stimulation is done only if requested by the health care provider because it could cause a vagal response, manifested by severe bradycardia and syncope.*

! NURSING SAFETY PRIORITY

Critical Rescue

Observe the patient with an upper SCI (above the level of T6) for signs of autonomic dysreflexia (hyperreflexia). Although it does not occur frequently, **autonomic dysreflexia** is an excessive, uncontrolled sympathetic output. It is characterized by severe hypertension, bradycardia, severe headache, nasal stuffiness, and flushing ([Chart 45-9](#)). The cause of this syndrome is a noxious stimulus—usually a distended bladder or constipation. *This is a neurologic emergency and must be promptly treated to prevent a hypertensive stroke!* [Chart 45-10](#) lists emergency care for autonomic dysreflexia.

Adjusting to Major Life Change

Planning: Expected Outcomes. The patient with an SCI is expected to adapt to a significant life change.

Interventions. Information obtained from the psychosocial assessment is used by the interdisciplinary team to identify strategies to help the patient adjust to the disability. Help the patient set realistic goals and verbalize feelings about the injury and his or her future. Invite the patient to ask questions, and answer them openly and honestly. Questions about prognosis and potential for complete recovery are referred to the health care provider because the timing and extent of recovery are different for each patient.

Collaborate with the case manager or discharge planner for a review of the patient’s insurance and financial status. Many insurance policies do not cover extended rehabilitation

CHART 45-9 KEY FEATURES

Autonomic Dysreflexia

- | | |
|---|---------------------------|
| • Sudden onset of severe, throbbing headache | • Nasal stuffiness |
| • Severe, rapidly occurring hypertension | • Sweating |
| • Bradycardia | • Nausea |
| • Flushing above level of lesion (face and chest) | • Blurred vision |
| • Pale extremities below level of lesion | • Piloerection |
| | • Feeling of apprehension |

CHART 45-10 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient Experiencing Autonomic Dysreflexia: Immediate Interventions

- Place patient in sitting position (first priority!).
- Page/notify health care provider.
- Loosen tight clothing on the patient.
- Assess for and treat the cause.
- Check the urinary catheter tubing (if present) for kinks or obstruction.
- If a urinary catheter is not present, check for bladder distention and catheterize immediately if indicated.
- Place anesthetic ointment on tip of catheter before insertion.
- Check the patient for fecal impaction; if present, disimpact immediately using anesthetic ointment.
- Check the room temperature to ensure that it is not too cool or drafty.
- Monitor blood pressures every 10 to 15 minutes.
- Give nitrates or hydralazine (Apresoline, Novo-Hylazin ) as prescribed.

services. Therefore other sources, including private foundations and donations, may be needed.

Community-Based Care

Case managers are ideal care coordinators to act as SCI patient advocates. In some settings, case managers begin working with patients in the emergency department to establish a positive image of SCI rehabilitation. Rehabilitation begins in the critical care unit when patients are hemodynamically stable and spinal shock has subsided. They are usually transferred from the acute care setting to a rehabilitation setting, where they learn more about self-care, mobility skills, and bladder and bowel retraining. The length of stay in the rehabilitation hospital or unit is typically 1 to 2 months, depending on the medical complications that may occur, such as infections.

Psychosocial adaptation is one of the critical factors in determining the success of rehabilitation. The case manager or acute care nurse can help the patient prepare for discharge or transfer to a rehabilitation hospital. Assist in verbalizing feelings and fears about body image, self-concept, role performance, self-esteem, and sexuality. The patient should be told about the expected reactions of those outside the security of the hospital environment. Role-playing or anticipating responses to potential problems is helpful. For example, the patient can practice answering questions from children about why he or she is in a wheelchair or cannot move certain parts of the body.

Many patients are concerned about their ability to have sexual intercourse and have children. Most hospitals do not have psychological social workers or counselors to discuss sexuality issues. Rehabilitation programs often include a sexuality/intimacy counselor as part of the interdisciplinary team approach to patient care.

Home Care Management

If the patient is discharged home or returns home for a weekend visit from the rehabilitation setting, the environment must be assessed to ensure that it is free from hazards and can accommodate the patient's special needs (e.g., a wheelchair). The occupational or physical therapist, in

collaboration with rehabilitation and the home care nurse, usually assesses the patient's temporary or permanent home environment. Ease of accessibility is particularly important at the entrance of the home as well as the bathroom, kitchen, and bedroom. The height of the patient's bed may need to be adjusted to allow a smooth transfer into and out of the bed.

All adaptive devices that the patient will use at home should be requested and delivered to the rehabilitation facility. This enables the nurse and other therapists to ensure that the items fit correctly and that the patient and family know how to use them correctly.

Teaching for Self-Management

The teaching plan for the patient with an SCI includes:

- Mobility skills (including skin care)
- ADLs skills
- Bowel and bladder retraining program
- Drug therapy
- Sexuality education

This information should be reinforced with written handouts, CDs, DVDs, or other patient education material that the patient and family members can use after discharge to the home. [Chart 45-11](#) provides information about aging for middle-aged and older adults with a spinal cord injury.

A full-time caregiver or personal assistant is sometimes required if the patient with tetraplegia returns home. The caregiver may be a family member or a nursing assistant employed to help provide care and companionship. A patient who is paraplegic is often able to function without assistance after an appropriate rehabilitation program.

Patients with cervical or high thoracic spinal cord injuries are discharged home or to a rehabilitation setting with a halo vest. A halo vest has a significant physical and psychological impact on patients. Physically, patients find it difficult to perform *mobility skills and ADLs* independently, especially dressing, bathing, and feeding. From a psychological perspective, patients perceive an altered body image. Teach the patient or other caregiver going home or to a rehabilitation setting how to care for and adjust to the halo device ([Chart 45-12](#)).

The ADLs training for the patient with an SCI includes a structured exercise program to promote strength and endurance. The occupational therapist instructs the patient in the correct use of all adaptive equipment. In collaboration with the therapists, instruct family members or the caregiver in transfer skills, feeding, bathing, dressing, positioning, and skin care as discussed briefly in this chapter and in more detail in [Chapter 8](#).

! NURSING SAFETY PRIORITY

Drug Alert

Teach the SCI patient and his or her family or other caregiver about the name, purpose, dosage, timing of administration, and side effects of all *drugs*. Make sure they understand the possible interaction of prescribed drugs with over-the-counter drugs or alcohol and illegal drugs.

Sexual function after spinal cord injury depends on the level and extent of injury. Incomplete lesions allow some control over sensation and motor ability. Complete lesions disconnect the messages from the brain to the rest of the body, and vice versa. However, men with injuries above T6 are often able to have erections by stimulating reflex activity.

CHART 45-11 NURSING FOCUS ON THE OLDER ADULT

What Patients Need to Know About Aging with Spinal Cord Injury

NURSING INTERVENTION	RATIONALES
Get flu shots annually, tetanus shots every 10 years, and the pneumonia vaccine as required.	Respiratory complications are the most common cause of death after spinal cord injury (SCI).
For women, have Papanicolaou (Pap) smears and mammograms as recommended by the American Cancer Society or your health care provider.	Limitations in movement may make breast self-examination difficult.
Take measures to prevent osteoporosis, such as increasing calcium intake and avoiding caffeine and smoking.	Women older than 50 years often lose bone density, which can result in fractures. Men can also have osteoporotic fractures as a result of immobility.
Practice meticulous skin care, including moisturizing and drinking plenty of water.	As a person ages, skin becomes dry and less elastic, predisposing the patient to pressure ulcers.
Take measures to prevent constipation, such as drinking adequate fluids, eating a high-fiber diet, stool softeners, and establishing a regular time for bowel elimination.	Constipation is a problem for most patients with SCI, and they are more likely to develop the problem later in life.
Modify activities if joint pain occurs; use a powered rather than a manual wheelchair. Ask the health care provider about treatment options.	Arthritis occurs in more than half of people older than 65 years. Patients with SCI are more likely to develop arthritis as a result of added stress on the upper extremities when using a wheelchair.

For example, stroking the penis will cause an erection. Ejaculation is less predictable and may be mixed with urine. However, urine is sterile, so the patient's partner will not get an infection.

Women with an SCI have a different challenge because they have indwelling urinary catheters more commonly than men with an SCI. However, some women do become pregnant and have full-term children. For others, ovulation stops in response to the injury. In this case, alternate methods for pregnancy, such as in vitro fertilization, may be an option. Some women also report vaginal dryness. Recommend a water-soluble lubricant for both partners to promote comfort.

For patients who choose not to have intercourse, intimate pleasure can be achieved in other ways, including kissing, hugging, fondling, masturbation, and oral sex. Variations in positioning may be needed to accommodate weak or paralyzed parts of the body. An understanding partner can help the patient adjust to his or her physical changes.

Health Care Resources

Refer the patient and family to local, state or province, and national organizations for more information and support for patients with SCI. These organizations include the National Spinal Cord Injury Association (www.spinalcord.org). Many excellent consumer-oriented books, journals, and DVDs are

CHART 45-12 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

*Use of a Halo Device**

- Be aware that the weight of the halo device alters balance. Be careful when leaning forward or backward.
- Wear loose clothing, preferably with hook and loop (Velcro) fasteners or large openings for head and arms.
- Bathe in the bathtub, or take a sponge bath. (Some physicians allow showers.)
- Wash under the lambswool liner of the vest to prevent rashes or sores; use powders or lotions sparingly under the vest.
- Have someone change the liner if it becomes odorous.
- Support the head with a small pillow when sleeping to prevent unnecessary pressure and discomfort.
- Try to resume usual activities to the extent possible; keep as active as possible. (The weight of the device may cause fatigue or weakness.) However, avoid contact sports and swimming.
- Do not drive because vision is impaired with the device.
- Keep straws available for drinking fluids.
- Cut meats and other food into small pieces to facilitate chewing and swallowing.
- Before going outside in cold temperatures, wrap the pins with cloth to prevent the metal from getting cold.
- Have someone clean the pin sites as recommended by physician or hospital protocol.
- Observe the pin sites daily for redness, drainage, or loosening; report changes to the physician.
- Increase fluids and fiber in the diet to prevent constipation.
- Use a position of comfort during sexual activity.

*Home care instructions may vary depending on hospital or physician preference.

DECISION-MAKING CHALLENGE

Safety, Evidence-Based Practice, Teamwork and Collaboration

A 36-year-old man who has had an L-3 spinal cord injury for 14 years is admitted for septicemia. He has a large, stage 4 pressure ulcer on his left buttock and an indwelling urinary catheter. The patient has been living alone for the past 3 years since his wife left him. He states he has been in and out of hospitals for a variety of problems and is tired of living. The patient states he works as a car mechanic at his house. He seldom leaves his home and has no significant other in his life at this time. An antidepressant was prescribed for the patient last year, but he does not take it because it makes him tired.

1. What priority problems does this patient have at this time? Which problems need immediate action and why? What other data do you need to help formulate your answer?
2. With what members of the interdisciplinary and nursing team should you collaborate to provide quality care for this patient?
3. What may be causing the patient's septicemia? What are the evidence-based interventions for the care of patients with septicemia? Use a reliable electronic database to help you answer this question.
4. Use the SBAR method to communicate your concerns about this patient to another nurse who will be continuing his care.

also available. Support groups may help the patient and family adjust to a changed lifestyle and provide solutions to commonly encountered problems.

The primary purpose of rehabilitation is to enable patients to function independently in their communities. However, many physical barriers still exist in some communities that prevent the patient in a wheelchair from finding a parking place, using sidewalks, and attending activities or utilizing

FIG. 45-6 Community physical barrier example: The patient cannot use a wheelchair to get onto the sidewalk.

resources (Fig. 45-6). The use of Photovoice (sometimes referred to as *Photo Voice*) projects can be very helpful in making positive changes in the community for people who are disabled.

Photovoice is a combination of photographs, videos, and storytelling that allows disabled people in the community to “voice our individual and collective experiences” in an organized way. This process can allow groups of patients with SCIs to work together to record and discuss their community’s strengths and concerns. The collective desired outcome for Photovoice is to influence policymakers to make changes that remove or change their community’s barriers. [Newman and SCI Photovoice Participants \(2010\)](#) described a Photovoice project to create a database of community environmental barriers and facilitators in a large city in the southeastern United States. Over 500 facilitators and over 500 barriers were identified. The authors produced a YouTube video and concluded that this type of community-based participatory project was extremely valuable to help wheelchair-bound SCI patients.

EVALUATION: OUTCOMES

Evaluate the care of the patient with an SCI based on the identified priority patient problems. The expected outcomes are that the patient:

- Exhibits no deterioration in neurologic status
- Maintains a patent airway, an alveolar exchange to maintain blood gases, and adequate ventilation
- Is free from complications of immobility
- Performs basic ADLs as independently as possible with or without the use of assistive/adaptive devices
- Achieves control of elimination of stool and urine
- Psychologically adapts to a significant life change

SPINAL CORD TUMORS

Pathophysiology

Spinal cord tumors occur most often in the thoracic area, but they can occur in the lumbar and cervical areas. These tumors are classified as either primary or secondary. Signs and

symptoms depend on the location of the tumor and its speed of growth. Tumors that involve the bones of the vertebral column usually occur as a result of metastasis (cancer spread) from other areas of the body.

The pathologic effects of a spinal cord tumor are more often related to compression of the cord than to invasion of the spinal cord itself. As the tumor expands within the vertebral column, it compresses the cord or the spinal nerve roots. Further growth leads to movement of the cord. In addition, a large tumor may affect the blood supply to the cord by compression or obstruct the normal flow of cerebrospinal fluid (CSF). Venous occlusion by the tumor may lead to spinal cord congestion and infarction (tissue death).

The appearance of neurologic signs and symptoms is related to the rate of tumor growth. The spinal cord can often accommodate a slowly growing lesion. With time, the cord may become significantly misshapen and displaced, but the patient has surprisingly few symptoms. However, a rapidly growing tumor quickly leads to spinal cord compression and edema and the development of neurologic symptoms, such as numbness and paralysis.

Primary spinal cord tumors involve the epidural vessels, spinal meninges, or glial cells of the cord. Their cause is unknown, but they can be cancerous or benign. Anatomically, spinal cord tumors may be extramedullary or intramedullary. **Intramedullary tumors** account for a small number of spinal cord tumors and are usually cancerous. They start within the spinal cord itself, in the central gray matter.

Secondary spinal cord tumors are more common. They develop as a result of a metastasis of a cancer that originated from another part of the body. The metastasis compresses the spinal cord or nerve roots from the outside.

Extramedullary tumors, representing most spinal cord tumors, are found within the spinal dura but outside the cord. They are further defined anatomically as extradural and intradural tumors. *Extradural or epidural* tumors occur between the vertebrae and the spinal dura. They develop in the surrounding bone and cause destruction of the vertebral bodies. *Intradural* tumors are located within the dura and originate from the pia-arachnoid, spinal roots, or ligaments.

Tumors involving the bones of the vertebrae typically develop as a consequence of *metastatic* tumors from the lungs, breasts, prostate, colon, and uterus.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The clinical manifestations of a spinal cord tumor depend on its location ([Chart 45-13](#)) and rate of growth. The most common problem is pain. Pain results from spinal cord compression, infiltration of the spinal tracts, or irritation of the spinal roots. Assess the quality, severity, and intensity of the pain. In addition, ask the patient to describe factors that worsen and relieve the pain. **Radicular** (nerve root) pain is stabbing or dull, with intermittent episodes of sharp, piercing pain. The pain may increase during coughing, straining, or sneezing. Lying flat may increase the pain as a consequence of stretching the involved spinal nerve roots.

Involvement of the corticospinal tract may lead to mobility problems. Assess for weakness, clumsiness, spasticity, and

hyperactive reflexes, and compare responses on both sides of the body. Other presenting signs include ataxia (staggered gait), hypotonia (decreased muscle tone), and a positive Babinski's reflex. Spastic paralysis occurs most often, although a flaccid paralysis may be present in a tumor that affects the spinal roots, an intramedullary tumor in the lumbosacral area, or an extramedullary tumor.

Determine sensory loss on each side of the body, and compare the responses. Early symptoms include a slowly progressive numbness or tingling, pain, and temperature loss. The sensory deficit is further marked by a decreased touch perception, an inability to sense vibration, and a loss of position sense. The patient often reports a tight, bandlike feeling around the trunk.

Loss of bladder control often occurs before a loss of bowel control. Assess for urinary hesitancy, dribbling, incontinence, urgency, or acute retention. Bowel dysfunction is manifested by constipation. Keep in mind that the patient is often embarrassed to admit to bladder or bowel dysfunction.

A lesion in the sacral area may cause a decrease in genital sensation and thus affect the patient's sexual function and enjoyment. Men may be unable to have an erection or to ejaculate.

Radiographic examinations or scans of the spine are obtained to detect a narrowing of the spinal canal, destruction of the vertebrae, or the presence of calcification. A myelogram may be useful when a block is incomplete; it indicates the level, extent, and boundaries of a tumor. This test is being performed less today because of newer imaging techniques.

A biopsy may be done to diagnose the specific type of tumor using a CT/MRI-guided needle. A biopsy is not needed for tumors that result from metastases if cancer has been diagnosed in another site of the body.

An MRI scan with and without contrast medium provides more detail of the pathologic condition of the spinal cord than either a CT scan or myelography. Electromyography (EMG) may help make a differential diagnosis to rule out multiple sclerosis (MS) or amyotrophic lateral sclerosis (ALS).

INTERVENTIONS

Nursing care of the patient with a spinal cord tumor focuses on careful monitoring of vital signs and neurologic status at least every 4 hours or more often if clinically indicated.

! NURSING SAFETY PRIORITY

Critical Rescue

For the patient with a spinal cord tumor, report any change in motor and sensory status immediately to the physician or Rapid Response Team. Swelling or tumor invasion can damage the spinal nerves that help control the diaphragm, and respiratory failure can result.

The primary management of a spinal cord tumor is *surgery*. The desired outcome of surgical intervention is to remove as much of the tumor as possible. Often, this is not possible and other treatment is needed (e.g., radiation therapy). *Emergency surgery is performed if the patient has a rapid loss of motor and sensory function or a loss of bladder and bowel control. Surgical decompression may be performed to maintain bladder, bowel, or motor function and to preserve quality of life—even with a poor prognosis.*

The neurosurgeon performs a laminectomy and surgical decompression and total or partial resection of the tumor. Depending on the extent of the tumor, a spinal fusion may be necessary. Rarely, a cordotomy or a palliative sectioning of sensory roots is done to control intractable pain.

After surgery, assess the patient's vital signs and neurologic status every 1 to 2 hours until they are stable and then every 4 hours. Help turn the patient as a unit (log roll) and reposition every 2 hours. Inspect the incision site for drainage, especially for cerebrospinal fluid (CSF), and signs of infection. Carefully monitor the patient with a cervical cord tumor for respiratory compromise. Postoperative nursing care for a patient undergoing a laminectomy is discussed on p. 964 under Postoperative Care in the Back Pain section of this chapter.

Radiation therapy may be necessary, depending on the tumor type. It is usually used with low-grade malignant tumors that are not completely removed, with metastatic tumors, or with recurrent tumors when there is no other treatment option. The spinal cord cannot tolerate high doses of radiation. Overexposure to radiation may lead to spinal damage, which can develop over 6 to 12 months of therapy. Radiation overdose is manifested by progressive spinal cord degeneration and neurologic deficits. With time, the patient experiences spastic paralysis, loss of sensation, and bowel and bladder dysfunction. Death may occur. Care of the patient undergoing radiation therapy is described in detail in [Chapter 24](#).

The use of chemotherapy in the treatment of spinal cord tumors is very limited. The drugs that are given tend to be alkylating agents, effective for some central nervous system (CNS) tumors because they cross the blood-brain barrier. Some patients may receive carmustine (BCNU) or lomustine (CCNU). In some cases, combination chemotherapy with

CHART 45-13 KEY FEATURES

Spinal Cord Tumors

General Manifestations

- Pain
- Sensory loss or impairment
- Motor loss or impairment
- Sphincter disturbance (bladder before bowel)

Cervical Manifestations

High Cervical

- Respiratory distress
- Diaphragm paralysis
- Occipital headache
- Quadriplegia
- Stiff neck
- Nystagmus
- Cranial nerve dysfunction

Low Cervical

- Pain in the arms and the shoulders
- Weakness
- Paresthesia
- Motor loss
- Horner's syndrome
- Increased reflexes

Thoracic Manifestations

- Sensory loss
- Spastic paralysis
- Positive Babinski's sign
- Bladder and bowel dysfunction
- Pain in the chest and the back
- Muscle atrophy
- Muscle weakness in the legs
- Foot drop

Lumbosacral Manifestations

- Low back pain
- Paresis
- Spastic paralysis
- Sensory loss
- Bladder and bowel dysfunction
- Sexual dysfunction
- Decreased-to-absent ankle and knee reflexes

procarbazine, vincristine, and carmustine is used (PVC therapy). Chemotherapy may also be used as an adjunctive therapy for tumors metastasized to the spinal cord from other primary sites, such as the breast. Meningeal involvement may benefit from intrathecal (spinal) chemotherapy. [Chapter 24](#) describes the general nursing care associated with giving chemotherapy.

Community-Based Care

Collaborate with the patient and his or her family members or significant others to identify and suggest ways to eliminate potential hazards in the home. If needed, make a referral to a home care nurse, social worker, or case manager to assess the need for structural alterations to the home. Alterations may be needed to accommodate ambulatory aids (e.g., a walker) and to help the patient to perform ADLs.

Depending on the prognosis, some patients are discharged from the acute care hospital to a rehabilitation setting, where they can learn to function as independently as possible. [Chapter 8](#) describes rehabilitation in detail.

The teaching plan for the patient with a spinal cord tumor depends on his or her level of dysfunction. With decompression of the tumor, the severity of the patient's symptoms often lessens. Deficits that may remain include mobility and sensory loss. Learning mobility skills can enable the patient to negotiate movement on sidewalks, carpeting, and other flooring surfaces. The patient must also be able to negotiate sidewalk curbs independently. The physical or occupational therapist instructs the patient in the correct use of all adaptive equipment. Review the individualized bowel and bladder program with the patient, family member, or other caregiver. [Chapter 8](#) describes these programs and the rehabilitation process in detail.

The desired outcome of sexuality education in the acute care setting is to answer questions and correct any misinformation. Unless the nurse has had specific training or experience in sexuality counseling of people with spinal cord tumors or injuries, more detailed questions should be directed to a sexuality counselor.

The prognosis for the patient with malignant tumors or metastatic tumors is poor. Determine what the physician and family members have told the patient about diagnosis and prognosis. Encourage the patient to verbalize feelings and fears about prognosis, body image, self-concept, role performance, and self-esteem.

Refer patients and family members to local, state or province, and national organizations for people with spinal cord injuries. These groups often have information and support groups for patients with spinal cord tumors. Refer patients with a malignancy to the American Cancer Society (www.cancer.org). Referral to support groups may also assist families with helping the patient adapt to lifestyle changes. The Canadian Cancer Society (www.cancer.ca) offers similar services.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a chronic autoimmune disease that affects the myelin sheath and conduction pathway of the central nervous system (CNS). It is one of the leading causes of neurologic disability in young adults. This chronic disease is characterized by periods of remission and **exacerbation**

(flare). Patients progress at different rates and over different lengths of time. However, as the severity and duration of the disease progress, the periods of exacerbation become more frequent. Patients with MS have a normal life expectancy as long as the effects of the disease are treated.

A major concern reported by most patients is how long it takes to establish a diagnosis of MS. Many patients go to several health care providers, are given varying diagnoses and treatment, and/or are told that their symptoms are related to stress and anxiety. The patient and family are often relieved to have a definite diagnosis but may express anger and frustration that it took a long time to start appropriate treatment. Therefore establish open and honest communication with the patient and allow him or her to share frustrations, anger, and anxiety.

Pathophysiology

Multiple sclerosis is characterized by an inflammatory response that results in diffuse random or patchy areas of **plaque** in the white matter of the CNS. When this occurs, the myelin sheath is damaged and its thickness is reduced, or **demyelinated**. Myelin is responsible for the electrochemical transmission of impulses between the brain and spinal cord and the rest of the body. Impulses are still transmitted but are not as effective as before. Over time, they may be completely blocked. The white fiber tracts (axons) that connect the neurons in the brain and spinal cord are generally involved in MS. The areas particularly affected include optic nerves, pyramidal tracts, posterior columns, brainstem nuclei, and the ventricular region of the brain. Eventually, with repeated exacerbations of the disease, damage to the axons becomes permanent.

The four major types of MS include (McCance et al., 2010):

- Relapsing-remitting
- Primary progressive
- Secondary progressive
- Progressive-relapsing

The classic picture of the **relapsing-remitting** type of **MS (RRMS)** occurs in most cases of multiple sclerosis. The course of the disease may be mild or moderate, depending on the degree of disability ([Palmieri, 2008](#)). Symptoms develop and resolve in a few weeks to months, and the patient returns to baseline. During the relapsing phase, the patient reports loss of function and the continuing development of new symptoms.

Primary progressive MS (PPMS) involves a steady and gradual neurologic deterioration without remission of symptoms. The patient has progressive disability with no acute attacks. Patients with this type of MS tend to be between 40 and 60 years of age at onset of the disease.

Secondary progressive MS (SPMS) begins with a relapsing-remitting course that later becomes steadily progressive. About half of all people with RRMS developed SPMS within 10 years. The current addition of disease-modifying drugs as part of disease management may decrease the development of SPMS.

Progressive-relapsing MS (PRMS) is characterized by frequent relapses with partial recovery but not a return to baseline. This type of MS is seen in only a small percentage of patients ([Palmieri, 2008](#)). Progressive, cumulative symptoms and deterioration occur over several years.

Etiology and Genetic Risk

The exact cause of MS remains unknown and is very complex. Research continues on viral, immunologic, genetic, and environmental etiologic factors. Viruses are well recognized as causes of demyelination and inflammation. Therefore it may be possible that a virus or other infectious agent is the triggering factor in MS. Although a number of viruses have been studied, no single virus has been identified as causing MS in genetically predisposed people. The environment may also contribute to the development of MS. The disease is seen more often in the colder climates of the northeastern, Great Lakes, and Pacific northwestern states, as well as in Canada.

Large genome studies of families have helped identify familial patterns of multiple sclerosis. For example, having a first-degree relative such as a parent or sibling with MS increases a person's risk for developing the disease. Recent research also confirms the association of multiple sclerosis (MS) with the interleukin (IL)-7 and IL-2 receptor genes. Other interleukin genes, B-lymphocytes, and B-cells play a role in more progressive forms of the disease (McCance et al., 2010). These data help guide development of targeted drug therapies that may cure or better manage MS.

Incidence/Prevalence

MS usually occurs in people between the ages of 20 and 40 years, but cases may occur in those younger than 15 years and older than 50 years. About 400,000 people in the United States have MS, and women are affected about twice as often as men. The disease affects 2.5 million people worldwide. Although MS tends to occur more frequently among whites, it affects people of all races (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Multiple sclerosis (MS) often looks like other neurologic diseases, which can make the diagnosis difficult and prolonged. As a result, patients often see many health care providers and undergo a variety of diagnostic tests and treatments. Obtaining a thorough history is essential for accurate diagnosis. Ask about a history of vision, mobility, and sensory changes, all of which are early indicators of MS. Symptoms are often vague and nonspecific in the early stages of the disease and may disappear for months or years before returning. Ask about the progression of symptoms. Pay particular attention to whether the symptoms are intermittent or are becoming progressively worse. Document the date (month and year) when the patient first noticed the clinical manifestations.

Next, ask about factors that aggravate the symptoms, such as fatigue, stress, overexertion, temperature extremes, or a hot shower or bath. Ask the patient and the family about any personality or behavioral changes that have occurred (e.g., euphoria [very elated mood], poor judgment, attention loss). In addition, determine whether there is a family history of MS.

Physical Assessment/Clinical Manifestations

Multiple sclerosis produces a wide variety of manifestations (Chart 45-14). Any myelinated fibers of the brain and spinal cord may be affected. To determine a patient's specific

manifestations, perform a complete neurologic assessment as described in Chapter 43.

First, assess the patient's ability to move. The patient often reports increased fatigue and stiffness of the extremities, particularly the legs. Fatigue is one of the most disabling manifestations, affecting almost all patients with MS. Unlike fatigue in other patients, MS fatigue is associated with continuous sensitivity to temperature.

Flexor spasms at night may awaken the patient from sleep. Further examination reveals increased or hyperactive deep tendon reflexes, positive Babinski's reflex, and absent abdominal reflexes. Gait may be unsteady because of leg weakness and spasticity due to cerebral motor strip damage.

Significant *cerebellar* findings include **intention tremor** (tremor when performing an activity), **dysmetria** (inability to direct or limit movement), and **dysdiadochokinesia** (inability to stop one motor impulse and substitute another). Motor movements are often clumsy. The patient may lose balance easily and may exhibit signs of poor coordination.

During examination of the *cranial nerves* and brainstem function, ask the patient if he or she has or has had episodes of tinnitus (ringing in the ears), vertigo (dizziness), and hearing loss. Assess for facial weakness and dysphagia. Speech problems include dysarthria (slurred speech) and slow, scanning speech.

Typical clinical findings from assessment of the patient's visual acuity, visual fields, and pupils include:

- Blurred vision
- **Diplopia** (double vision)
- Decreased visual acuity
- **Scotomas** (changes in peripheral vision)
- **Nystagmus** (involuntary rapid eye movements)

Sensory findings include hypalgesia (diminished sensitivity to pain), paresthesia, facial pain, and decreased temperature perception. The patient may report numbness, tingling, burning, or crawling sensations.

If demyelination of the *spinal cord* has occurred, the patient may experience bowel and bladder dysfunctions. The patient may have an areflexic bladder or may experience frequency, urgency, or nocturia. Ask the patient if he or she has constipation or incontinence. Inquire about problems with

CHART 45-14 KEY FEATURES

Multiple Sclerosis

- Muscle weakness and spasticity
- Fatigue
- Intention tremors
- Dysmetria (inability to direct or limit movement)
- Numbness or tingling sensations (paresthesia)
- Hypalgesia (decreased sensitivity to pain)
- Ataxia (decreased motor coordination)
- Dysarthria (slurred speech)
- Dysphagia (difficulty swallowing)
- Diplopia (double vision)
- Nystagmus (involuntary eye movements)
- Scotomas (changes in peripheral vision)
- Decreased visual and hearing acuity
- Tinnitus (ringing in the ears), vertigo (dizziness)
- Bowel and bladder dysfunction
- Alterations in sexual function, such as impotence
- Cognitive changes, such as memory loss, impaired judgment, and decreased ability to solve problems or perform calculations

EVIDENCE-BASED PRACTICE

What Effect Does Multiple Sclerosis Have on Sexual Function?

Fraser, C., Mahoney, J., & McGurl, J. (2008). Correlates of sexual dysfunction in men and women with multiple sclerosis. *Journal of Neuroscience Nursing*, 40(5), 312-317.

Sexual dysfunction (SD) is a disability that is often not addressed. The purpose of this study was to investigate the relationship between SD and other symptoms that are experienced by patients with multiple sclerosis (MS). The sample included 32 men and 219 women who volunteered to complete a valid and reliable assessment tool designed to measure neurologic disability. The strongest variable for both men and women that affected SD was fatigue. The results also revealed that the most common problems for women with MS included lack of vaginal lubrication and orgasm.

Level of Evidence: 4

The research design was a descriptive study using volunteer subjects.

Commentary: Implications for Research and Practice

Although the findings of this study cannot be generalized, they validate the concerns of patients with multiple sclerosis regarding SD. Sexual dysfunction affects a person's quality of life. Nurses need to address issues related to SD and, if needed, refer patients or couples for sexual counseling. More research on this topic is needed to help patients with disabilities have an improved quality of life.

sexuality, including impotence, difficulty sustaining an erection, and decreased vaginal secretions.

Psychosocial Assessment

Assess the patient for mental status changes. Cognitive changes are usually seen late in the course of the disease and include decreased short-term memory, concentration, and ability to perform calculations; inattentiveness; and impaired judgment.

After the initial diagnosis of MS, the patient is often anxious. Apathy, emotional lability, and depression are common problems that occur later. The patient may be euphoric or giddy, either as a result of the disease itself or because of the drugs used to treat the disease. Assess the patient's previously used coping and stress management skills in preparing him or her for a chronic, usually debilitating disease. Secondary depression is the most frequent mental health disorder diagnosed in people with MS.

Assess the impact of bowel and bladder problems. Managing fecal incontinence or constipation can be time-consuming and embarrassing. A study by Norton and Chelvanayagam (2010) found that elimination problems affected quality of life as much as mobility difficulties.

Sexual dysfunction (SD) is often not assessed in people with multiple sclerosis. Yet, it has a major impact on quality of life. In a study by Fraser et al. (2008), patients with MS reported that fatigue was the main reason for SD (see the Evidence-Based Practice box above). Assess the patient's fatigue level and pattern. Be sensitive when asking about the patient's sexual practices and orientation.

MS also affects the entire family due to the unpredictability and uncertainty of the course of the disease. Chronic fatigue may also prevent the patient from participating in family and community activities. Assess coping strategies of

family members or other caregivers, and help them identify support systems that can assist them as they live with the patient with MS.

Laboratory Assessment

No single specific procedure is definitively diagnostic for MS. However, the collective results of a variety of tests are usually conclusive. Abnormal cerebrospinal fluid (CSF) findings include an elevated protein level and a slight increase in the white blood cell count. CSF electrophoresis reveals an increase in the myelin basic protein and the presence of increased immunoglobulins, especially IgG. IgG bands are seen in most patients with MS.

Other Diagnostic Assessment

The health care provider usually requests a CT scan, which may show an increased density in white matter and MS plaques. MRI demonstrates the presence of plaques and is considered diagnostic for MS. A complete diagnostic evaluation is necessary to exclude other disease diagnoses.

Results of visual, auditory, and brainstem evoked potential studies are often abnormal. Electromyography (EMG) findings may be grossly abnormal in people with advanced disease.

INTERVENTIONS

The purpose of management is to modify the disease's effects on the immune system, prevent exacerbations, manage symptoms, and improve function. As with other spinal cord diseases, care of the patient with MS requires the collaborative efforts of the interdisciplinary team.

The patient with MS is often weak and easily fatigued. The Concept Map on p. 981 illustrates the priority problems and interventions for the patient with MS. Teach the patient the importance of planning activities and allowing sufficient time to complete activities. For example, the patient should check that all items needed for work are gathered before leaving the house. Items used on a daily basis should be easily accessible.

Drug Therapy

Current therapies are designed to treat the dysfunctional immune system that is associated with multiple sclerosis (MS). A variety of drugs are used to treat and control the disease, decrease specific symptoms, and attempt to slow its progression.

One or more of these drugs is recommended for early and continuous treatment of relapsing types of MS (Duddy et al., 2011; Ryan, 2009):

- Interferon-beta (Avonex, Betaseron, or Rebif)—immunomodulators that *modify* the course of the disease and have antiviral effects
- Glatiramer acetate (Copaxone)—a synthetic protein that is similar to myelin-based protein
- Natalizumab (Tysabri)—the first monoclonal antibody approved for MS that binds to WBCs to prevent further damage to the myelin

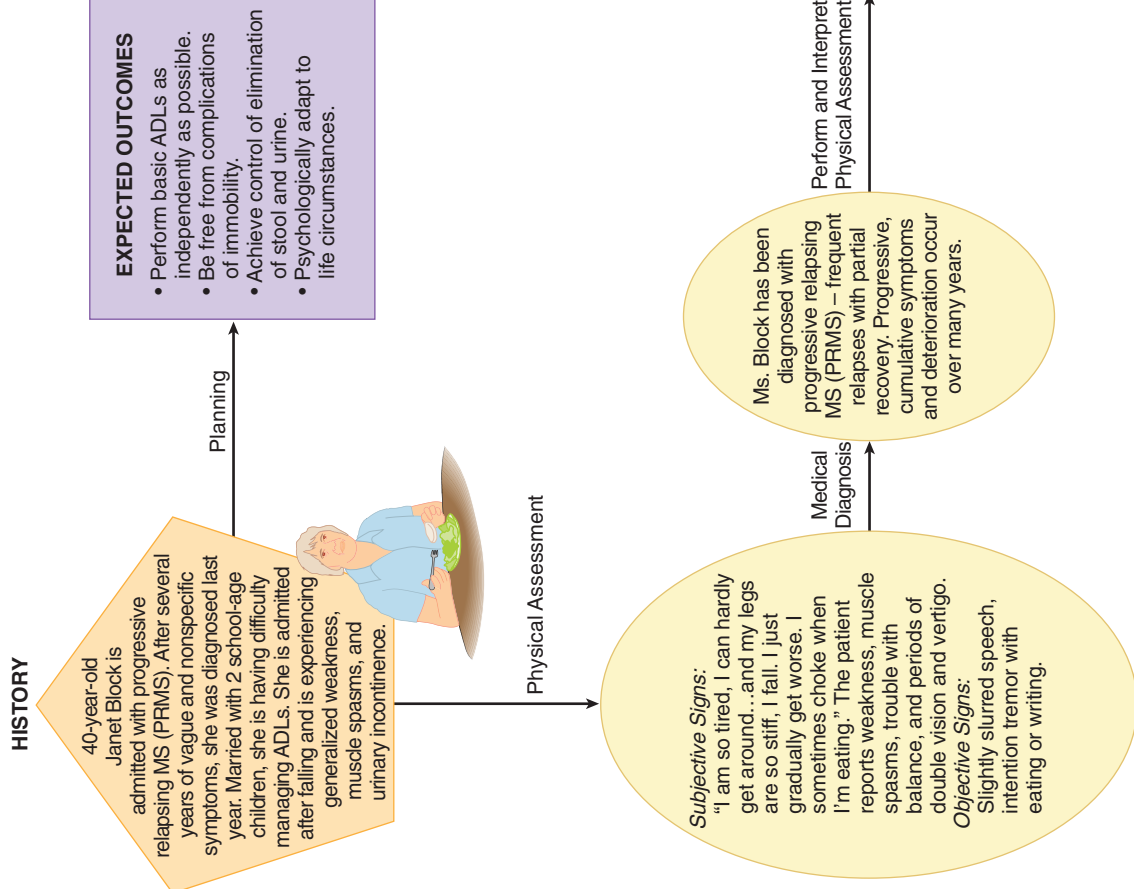

Both interferon-beta and glatiramer acetate are subcutaneous injections that patients can self-administer.

Natalizumab is a controversial drug because it can cause many adverse events. It is given as an IV infusion in a physician's office or clinic under careful supervision. The patient is monitored carefully for allergic or anaphylactic reaction when each dose is given because the drug tends to build up

Concept Map: Multiple Sclerosis

1 History Obtain a thorough history. Helps with accurate diagnosis. Ask the patient about vision, mobility, and sensory changes, which may be early indicators of MS. Symptoms are often vague and nonspecific in the early stages of the disease.	2 Nursing Safety Priority: Action Alert Monitor for fall risk. Assess the patient's ability to move, the presence of spasms, and stiffness of extremities. Assesses unsteadiness of gait due to leg weakness and spasticity. Motor movements are often clumsy. Loss of balance and poor coordination increase the risk for falls.	3 Activities Teach the patient about getting adequate rest, avoiding undue stress, and the importance of social activities. Addresses the anxiety about the length of remission or progression of the disease. Fatigue is the most disabling symptom and can decrease the patient's participation in life events.	4 Vision • Instruct the patient to wear an eye patch, alternating from eye to eye every few hours. Relieves diplopia. • Have the patient see an ophthalmologist. Changes in visual acuity may be aided by corrective lenses.	5 Bladder Care Assist with bladder care: drugs, intermittent self-catheterization, indwelling catheterization, or bladder pacemaker. Prophylactic antibiotics and increased fluids prevent UTIs. Demyelination of nerves affect function and can have a major impact on the patient's quality of life.	6 Psychosocial Assessment Assist the patient in verbalizing concerns about body image, self-concept, role performance, self-esteem, and sexuality. Help her set realistic goals. Establishes open and honest communication by allowing her to share her frustrations, anger, and anxiety.	7 Medications Provide written instructions and review prescribed medications. Reinforces the importance and purpose of drug regimen: Anticholinergics for bladder dysfunction; antispasmodics, antiepileptics, analgesics, NSAIDs, tranquilizers, and/or antidepressants for pain and paresthesia.	8 Dysarthria and Dysphagia Collaborate with a speech-language pathologist for evaluation and treatment of slurred speech and swallowing abilities. Evaluates and treats dysphasia, which often occurs with dysarthria.	9 Support Systems Assist the patient to identify support systems for family members as they live with the patient with MS. Teach family strategies to enable them to cope with these changes. Avoids embarrassment for the patient because personality changes are not unusual.	10 Health Teaching Give the patient a resource person to call from the National MS Society (www.nationalmssociety.org) and other resources, including meal delivery, transportation, and homemaker services. Assists the patient with ADLs.
---	--	--	---	---	--	---	---	--	---

INTERVENTIONS

! NURSING SAFETY PRIORITY**Drug Alert**

Teach patients how to give and rotate the site of interferon-beta and glatiramer acetate injections because local injection site (skin) reactions are common. The first dose of these drugs is given under medical supervision to monitor for allergic response, including anaphylactic shock. Teach patients receiving these drugs to avoid crowds and people with infections. Remind them to report any sign or symptom associated with infection immediately to their health care provider.

in the body. *Patients receiving this drug are at a high risk for progressive multifocal leukoencephalopathy (PML).* This opportunistic viral infection leads to death or severe disability. Monitor for neurologic changes, especially changes in mental state, such as disorientation or acute confusion. PML is confirmed by an MRI and examining the cerebrospinal fluid for the causative pathogen.

Natalizumab also causes damage to hepatic cells. Carefully monitor liver enzymes and teach patients to have frequent laboratory tests to assess for changes.

Mitoxantrone (Novantrone), a chemotherapy drug, has been shown to be effective in reducing neurologic disability. It also decreases the frequency of clinical relapses in patients with secondary progressive, progressive-relapsing, or worsening relapsing-remitting MS.

Fingolimod (Gilenya) is the first oral immunomodulator approved for the management of MS. The capsules may be taken with or without food. Teach patients to monitor their pulse every day because the drug can cause bradycardia, especially within the first 6 hours after taking it (Duddy et al., 2011).

Immunosuppressive therapy with a combination of cyclophosphamide (Cytoxan) and methylprednisolone (Solu-Medrol) may be used for some patients to stabilize the disease process and decrease inflammation. IV adrenocorticotrophic hormone (ACTH) may be given instead of methylprednisolone and tapered gradually over 2 to 4 weeks.

Promoting Mobility and Managing Symptoms

For symptom management, the health care provider may prescribe baclofen (Lioresal), diazepam (Valium, Apo-Diazepam ♣), or dantrolene sodium (Dantrium) to lessen muscle spasticity. Dalfampridine (Ampyra), a potassium channel blocker, is a new oral drug that can be prescribed to improve walking ability and speed. Dalfampridine is not given to patients with a history of seizures or renal disease.

Severe muscle spasticity may be treated with intrathecal baclofen (ITB) administered through a surgically implanted pump. Paresthesia may be treated with carbamazepine (Tegretol) or tricyclic antidepressants. Propranolol hydrochloride (Inderal) and clonazepam (Klonopin) have been used to treat cerebellar ataxia. If fatigue cannot be controlled through the use of nonpharmacologic measures, amantadine hydrochloride (Symmetrel) may be prescribed.

Bladder dysfunction (detrusor hyperreflexia) may be treated with anticholinergic agents. Pain and paresthesia are often problems for the MS patient. Antispasmodics, antiepileptic drugs (AEDs), analgesics, NSAIDs, tranquilizers, or antidepressants may be used, depending on the cause of the pain and the patient's response. Teach patients about side and adverse effects for drugs that they may need to help increase their quality of life.

In collaboration with physical and occupational therapists, plan an exercise program that includes range-of-motion (ROM) exercises and stretching and strengthening exercises. Emphasize the importance of avoiding rigorous activities that increase body temperature. Increased body temperature may lead to increased fatigue, diminished motor ability, and decreased visual acuity resulting from changes in the conduction abilities of the injured axons.

Cognitive impairment may occur early in the disease process. Many patients have some degree of neuropsychological dysfunction during the course of their disease. Areas affected include attention, memory, problem solving, auditory reasoning, handling distractions, visual perception, and use of speech.

! NURSING SAFETY PRIORITY**Action Alert**

For the patient with MS who has cognitive impairment, assist with orientation by placing a single-date calendar in his or her room. Give or encourage the patient to use written lists or recorded messages. To maintain an organized environment, encourage him or her to keep frequently used items in familiar places.

If the patient experiences dysarthria (slurred speech), refer him or her to the speech-language pathologist (SLP) for evaluation and treatment. It is not unusual for the patient with dysarthria also to have dysphagia (difficulty swallowing). The SLP performs a swallowing evaluation, but further diagnostic testing may be indicated.

Women report impaired genital sensation, diminished orgasm, and loss of sexual interest. Men most often report difficulty in achieving and maintaining an erection and delayed ejaculation. If able, answer the patient's questions, or refer the patient to a counselor or urologist with experience in the field of sexuality, intimacy, and disability.

The patient may experience a variety of bladder problems. In addition to drug therapy, other measures include an intermittent self-catheterization program, indwelling urinary catheter, or insertion of a bladder pacemaker. When the patient activates the control on the pacemaker, the bladder is stimulated and voiding is initiated. Patients with MS are at increased risk for urinary tract infections. Prophylactic antibiotics may be prescribed by the health care provider. Remind the patient to drink plenty of fluids unless contraindicated by other medical conditions.

An eye patch that is alternated from eye to eye every few hours usually relieves **diplopia** (double vision). For peripheral visual deficits, teach scanning techniques by having the patient move his or her head from side to side. Changes in visual acuity may be assisted by corrective lenses.

Complementary and Alternative Therapies

Patients with MS have reported a number of complementary and alternative therapies that have been successful in decreasing their symptoms. **Esmonde and Long (2008)** found that the six most used therapies for patients with MS were:

- Reflexology
- Massage
- Yoga
- Relaxation and meditation
- Acupuncture
- Aromatherapy

Chapter 2 in this text describes most of these therapies. Marijuana has been used by some patients to relieve the pain of muscle spasms and is now legal for medical use in several U.S. states. It is also now legal in Canada.

Community-Based Care

Home Care Management

To help the patient maintain maximum strength, function, and independence, continuity of care through an interdisciplinary team in both the rehabilitation and home setting is necessary. Admission to a rehabilitation center is brief but provides a program to improve functional ability. In collaboration with the case manager and occupational therapist, assess the patient's home before discharge for any hazards. Any items that might interfere with mobility (e.g., scatter rugs) are removed. In addition, care must be taken to prevent injury resulting from vision problems. Teach the patient and family to keep the home environment as structured and as free from clutter as possible. As the disease progresses, the home may need to be adapted for wheelchair accessibility. Any necessary assistive/adaptive device should be readily available before discharge from the hospital.

Teaching for Self-Management

The health care provider explains to the patient and family the development of MS and the factors that may exacerbate the symptoms. Emphasize the importance of avoiding overexertion, stress, extremes of temperatures (fever, hot baths, overheating, and excessive chilling), humidity, and people with infections. Explain all medications to be taken on discharge, including the time and route of administration, dosage, purpose, and side effects. Teach the patient how to differentiate expected side effects from adverse or allergic reactions, and provide the name of a resource person to call if questions or problems occur. Provide written instructions as a resource for the patient and caregivers at home.

The physical therapist develops an exercise program appropriate for the patient's tolerance level at home. The patient is instructed in techniques for self-care, daily living skills, and the use of required adaptive equipment, such as walkers and electric carts. Include information related to bowel and bladder management, skin care, nutrition, and positioning techniques. Chapter 8 describes in detail these aspects of chronic illness and rehabilitation.

Teach patients about the importance of obtaining adequate rest and avoiding undue stress. It is equally important for them to engage in regular social activities. Often patients are anxious and worry about how long the remission will last or when the disease will progress.

Because personality changes are not unusual, teach the family or significant others strategies to enable them to cope with these changes. For example, the family may develop a nonverbal signal to alert the patient to potentially inappropriate behavior. This action avoids embarrassment for the patient.

Health Care Resources

Resources required by the patient depend on the course of the disease and the complications that occur. Patients often are able to live completely independently, but they may need some assistance. In severe disease, placement in an assisted-living or long-term care facility may be the best alternative.

The population of young and middle-aged residents in these settings is increasing as people with chronic, disabling diseases live longer.

Refer the patient and family members or significant others to the local chapter of the National Multiple Sclerosis Society (www.nationalmssociety.org). Other community resources include meal delivery services (e.g., Meals on Wheels), transportation services for the disabled, and homemaker services.

AMYOTROPHIC LATERAL SCLEROSIS

Pathophysiology

Amyotrophic lateral sclerosis (ALS), also known as **Lou Gehrig's disease**, is an adult-onset upper and lower motor neuron disease. It is characterized by progressive weakness, muscle wasting, and spasticity that eventually leads to paralysis. Beginning in one area of the body, motor weakness and deterioration spread until the entire body is involved, including the ability to talk, swallow, and breathe. As a result of loss of lower motor neurons (LMNs) found in the spinal cord and brainstem, the muscles to which they connect weaken, atrophy, and die.

Loss or death of upper neurons (found in the brain) breaks their connections with LMNs, and spasticity occurs in the muscles. Death typically occurs within 3 years of diagnosis due to respiratory failure (Murphy et al., 2007). There is no known cause, no cure, no specific treatment, no standard pattern of progression, and no method of prevention. Unlike with many other neural degenerative diseases, the sensory and autonomic nervous systems are not involved. Cognitive and behavioral dysfunction may occur, although the exact cause and extent of this has not been established.

Amyotrophic lateral sclerosis commonly affects people between the ages of 40 and 60 years, but it may also begin in younger and older age-groups. The incidence increases with each decade of life. ALS is more common in men than in women. The cause of the disease is unknown but is likely due to interactions of genetic, viral, and environmental factors.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The clinical manifestations of ALS include fatigue, muscle atrophy, and weakness. Early symptoms are listed in Chart 45-15.

In addition to motor changes, cognitive changes may affect the thinking and planning processes. As the disease progresses, muscle atrophy, particularly of the trapezius and

CHART 45-15 KEY FEATURES

Early Clinical Manifestations of Amyotrophic Lateral Sclerosis

- Tongue atrophy
- Weakness of the hands and arms
- Beginning muscle atrophy of the arms
- **Fasciculations** (twitching) of the face
- Nasal quality of speech
- **Dysarthria** (slurred speech)
- **Dysphagia** (difficulty swallowing)
- Fatigue while talking

sternocleidomastoid muscles, develops. Eventually the respiratory muscles become involved, leading to respiratory compromise, pneumonia, and death.

Diagnosis is based on clinical and diagnostic test findings and by ruling out other causes of the motor changes. There is no specific test to diagnose ALS, but creatine kinase (CK) is increased. The electromyogram (EMG) demonstrates fibrillations and fasciculations of the muscles. A muscle biopsy specimen typically demonstrates small, angulated, atrophic fibers. Other diagnostic studies reveal motor strength deficits in serial muscle testing; abnormal pulmonary function test results, such as a decreased vital capacity (<2 L); and dysphagia (difficulty swallowing).

INTERVENTIONS

There is no known cure for ALS, but an interdisciplinary approach is needed for maintaining optimum functioning and end-of-life care.

Riluzole (Rilutek) is the only drug approved by the Food and Drug Administration for use with ALS patients. It is not a cure, but it does extend survival time. The usual dose is 50 mg twice daily. Teach patients to take the drug without food and when the stomach is empty. Teach the patient how to detect signs and symptoms of liver toxicity, such as vomiting and jaundice, that the drug may cause. Remind them to have frequent liver enzyme tests, such as alanine aminotransferase (ALT) and aspartate aminotransferase (AST), as directed by the health care provider.

The health care provider also prescribes drug therapy for pain, fatigue, spasticity, excessive secretions, sleep disturbances, and other complications as they occur. The interdisciplinary team collaborates with the patient and family to develop an individualized plan of care. The physical therapist and occupational therapist evaluate the patient's home and recommend modifications as the disease progresses. An exercise and mobility program is developed, and special equipment is obtained as needed to help with ADLs and mobility. Other interventions are directed toward preventing complications of immobility and promoting comfort.

The speech-language pathologist (SLP) evaluates the patient for speech and swallowing problems and makes recommendations as needed. The SLP teaches patients various adaptive strategies, such as techniques to help them speak

louder and more clearly. He or she works with the patient and family to develop a communication system to be used when the patient can no longer verbally communicate.

A nutrition consult may be needed to help with planning meals that the patient can swallow. The family is taught how to ensure that the patient obtains sufficient nutrients, fiber, and fluids. When the patient can no longer swallow, a feeding tube may be placed, depending on the patient's decision or advance directives. The dietitian can recommend the appropriate enteral feedings.

For symptomatic treatment of dyspnea and/or intractable pain, opioids alone or in combination with benzodiazepines if anxiety is present may be prescribed. Titrating the dosages against the clinical symptoms is less likely to cause life-threatening respiratory depression. For treating terminal restlessness and confusion because of hypercapnia, neuroleptics may be used (e.g., chlorpromazine [Thorazine, Chlorpromazine] 12.5 mg every 4 to 12 hours orally, IV, or rectally).

At some point, the patient will require respiratory support. Intermittent positive-pressure ventilation (IPPV) or bi-level positive airway pressure (BiPAP) may be used to aid breathing during sleep or full time. Mechanical ventilation enables the patient to breathe and prolongs survival; it does not alter progression of the disease. For this reason, many patients elect not to be placed on a mechanical ventilator, according to their wishes or advance directives. Teach the patient about the need for advance directives, such as a living will. Chapter 9 discusses end-of-life issues and hospice services in detail.

NURSING SAFETY PRIORITY

Action Alert

Refer the patient with amyotrophic lateral sclerosis to a hospice program for palliative care. The hospice team works closely with the family to ensure the patient's comfort and respiratory support. The team collaborates with the health care provider to ensure that the patient has the needed drug therapy and pain control, as well as quality of life for the patient and family.

Other community resources include clinics and other support services run by the ALS Association (www.alsa.org) or the Muscular Dystrophy Association (www.mda.org).

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing inadequate mobility and sensation as a result of spinal cord health problems?

- Weakness or paralysis of one or more extremities
- Report of decreased sensation in one or more extremities
- Muscle spasticity or flaccidity
- Forward bent position when ambulating
- Limp or altered gait
- Bladder incontinence or retention
- Bowel incontinence or retention
- Report of pain in back and/or in one or more extremities
- Difficulty breathing

What should you INTERPRET and how should you RESPOND to a patient experiencing inadequate mobility and sensation as a result of spinal cord health problems?

Perform and interpret physical assessment, including:

- Assessing airway patency and breathing pattern
- Assessing level of consciousness
- Taking vital signs
- Performing a complete physical assessment
- Performing a complete neurologic assessment
- Assessing level of pain

NURSING CONCEPT REVIEW—cont'd

Respond by:

- Establishing an airway as needed
- Stabilizing the spine by positioning until surgery or other treatment is provided
- Preparing for imaging assessment tests
- Providing pain medication as prescribed
- Inserting an indwelling urinary catheter
- Collaborating with the health care team, especially the physical therapist and the occupational therapist, if needed

On what should you REFLECT?

- Monitor the patient for changes in condition, including deterioration of neurologic status.
- Consider how to best collaborate with the health care team when caring for patients with spinal cord injury or illness.
- Think about family reaction to the injury or illness and what additional resources could have been used or should be used in the future.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- To help prevent back injury, use proper body mechanics as described in [Chart 45-5](#).
- For patients who have back surgery, observe the incision site for bleeding and cerebrospinal fluid leakage (clear fluid).
- Log roll patients having spinal surgery, especially those who have fusions.
- For patients with an SCI, assess airway *first!*
- Observe patients with spinal injuries and diseases for complications of immobility.
- Monitor respiratory status carefully in patients with amyotrophic lateral sclerosis. Patients experience respiratory failure in terminal stages of the disease. Consider their advance directives to assist in planning care.

Health Promotion and Maintenance

- Teach patients who have had spinal surgery to avoid lifting and driving and to use proper body mechanics.
- Teach overweight and obese patients the importance of losing weight to reduce back pain and strain.
- Refer patients to appropriate resources, such as a sexuality counselor or urologist, for sexual dysfunction resulting from illness or disease. Counsel them as needed about sexuality issues.
- Assess patients with spinal cord injury and disease for the need for adaptive/assistive devices to become independent in ADLs.
- Implement bowel and bladder retraining programs for patients with SCI and spinal diseases.

Psychosocial Integrity

- Recognize that spinal cord injury and progressive neurologic diseases, such as MS, require the patient to adjust to major life changes.

- Determine patient and family coping strategies to help patients adjust to spinal trauma or disease.
- Encourage patients to share their feelings about life-altering SCI or neurodegenerative disease.
- Refer patients with spinal cord cancer to appropriate resources, such as the American Cancer Society and its support groups.

Physiological Integrity

- Assess pain level in patients with back injury, including the nature of the pain and location.
- Provide complete neurologic assessment of patients with spinal cord health problems, including muscle assessment as described in [Chart 45-8](#).
- Implement drug and non-drug interventions for back pain, including analgesics, NSAIDs, and muscle relaxants. Suggest heat as an adjunct to medication.
- Provide postoperative care and discharge teaching for patients having cervical neck surgery as listed in [Chart 45-6](#).
- Implement interventions to prevent complications associated with immobility, including turning, early ambulation or transfers out of bed, and incentive spirometry.
- Monitor patients with cervical spinal injuries for manifestations of autonomic dysreflexia (see [Chart 45-9](#)).
- Provide emergency care for patients who experience autonomic dysreflexia as listed in [Chart 45-10](#).
- Assess patients with multiple sclerosis for clinical manifestations as listed in [Chart 45-14](#). Fatigue is the most common symptom.
- Provide supportive care for the patient with amyotrophic lateral sclerosis. Refer to hospice in the terminal stage of the disease.

Care of Patients with Problems of the Peripheral Nervous System

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with interdisciplinary health care team members when providing care for patients with Guillain-Barré syndrome (GBS) and myasthenia gravis (MG).
2. Identify community resources for peripheral nervous system (PNS) disorders for patients and families.

Health Promotion and Maintenance

3. Provide information to patients and families on common side effects and administration of drugs for PNS disorders.

Psychosocial Integrity

4. Plan interventions for patients with GBS and MG for promoting communication.

Physiological Integrity

5. Describe how to perform focused neurologic assessments for patients with PNS disorders.

6. Compare and contrast the pathophysiology and etiology of GBS and MG.
7. Prioritize nursing care for the patient with GBS or MG.
8. Differentiate between a myasthenic crisis and a cholinergic crisis.
9. Identify specific nursing actions regarding drug administration for the patient with MG.
10. Assess patients having a thymectomy for postoperative complications.
11. Plan and implement postoperative care for the patient undergoing peripheral nerve repair.
12. Identify risk factors for restless legs syndrome.
13. Compare trigeminal neuralgia and facial paralysis assessment findings.
14. Explain the role of drug therapy in managing the patient with trigeminal neuralgia and facial paralysis.
15. Identify the priority for care for patients with trigeminal neuralgia.

The peripheral nervous system (PNS) is composed of the spinal nerves, cranial nerves, and part of the autonomic nervous system. Its function is to provide communication from the brain and spinal cord to other parts of the body. Neuropathy or peripheral neuropathy (PN) is a global word that refers to any disease, disorder, or damage to the PNS. These health problems may be acute, such as Guillain-Barré syndrome, or chronic, such as diabetic neuropathy. Typical

clinical manifestations of neuropathy include pain, muscle cramps, and muscle weakness.

Acquired neuropathies are grouped into three broad categories: inflammatory, traumatic, or systemic. *Inflammatory* neuropathies such as Guillain-Barré syndrome can affect the entire peripheral nervous system. Trigeminal neuralgia is a type of neuropathy caused by *trauma* or damage to a single nerve—the trigeminal nerve. Examples of *systemic*

neuropathy are diabetic PN and chemotherapy-induced PN. Neuropathies that are part of or caused by systemic diseases or treatments are discussed elsewhere in this text. All of these PNS health problems cause impairments in the human needs of *mobility, sensation, or both*.

GUILLAIN-BARRÉ SYNDROME

Pathophysiology

Guillain-Barré syndrome (GBS) is an acute inflammatory demyelinating polyneuropathy (AIDP) that affects the peripheral nervous system, causing motor weakness and sensory abnormalities. It is an uncommon disorder, affecting both genders equally and peaking after age 55 years (Simmons, 2010). Euro-Americans have the disease more often than other racial or ethnic groups.

GBS may be referred to by a variety of other names, such as *acute idiopathic polyneuritis* and *polyradiculoneuropathy*. As a result of **demyelination** (destruction of the myelin sheath) of the peripheral nerves, *progressive motor weakness* and *sensory abnormalities* occur. Symptoms typically begin in the legs and spread to the arms and upper body. This is referred to as an **ascending paralysis**. Paralysis can increase in intensity until the muscles cannot be used at all and the patient is almost totally immobile. As a result, some patients require mechanical ventilation because of weak or paralyzed respiratory muscles. Healing occurs in reverse; the neurons affected last are the first to recover.

GBS is the result of a variety of related immune-mediated pathologic processes. The immune system starts to destroy the myelin sheath that surrounds the axons of the peripheral nerves or attacks the axons themselves. Segmental demyelination (the destruction of myelin between the nodes of Ranvier) is the major pathologic finding in GBS. This destruction affects the transmission of impulses from node to node by slowing it down. Also, the brain receives fewer sensory signals, affecting the patient's ability to feel textures, heat, and pain. On the other hand, the brain may receive altered signals that cause the tingling or "crawling-skin" sensation many patients report.

On microscopic examination, groups of lymphocytes are seen at the points of myelin breakdown, yet the axons usually remain intact. In some instances, secondary damage to the cell body, the neurilemma, or the axon occurs. This can delay recovery or result in permanent neurologic deficits.

Three stages make up the *acute* course of GBS:

- The *acute or initial period* (1 to 4 weeks), which begins with the onset of the first symptoms and ends when no further deterioration occurs
- The *plateau period* (several days to 2 weeks)
- The *recovery phase* (gradually over 4 to 6 months, maybe up to 2 years), which is thought to coincide with remyelination and axonal regeneration (Some patients do not completely recover and have permanent neurologic deficits, referred to as *chronic GBS*.)

The exact cause of GBS remains unclear. The patient often relates a history of acute illness, trauma, surgery, or immunization 1 to 3 weeks before the onset of neurologic manifestations. Other risk factors include an upper respiratory tract infection or GI illness and positive antibodies to cytomegalovirus or Epstein-Barr virus (EBV). It is believed that the

precipitating event or illness causes a limited malfunction of the immune system, which sensitizes the T-cells to the patient's myelin. In response to several antigens, some patients apparently form a demyelinating antibody that has a direct toxic effect on nerves or attracts a cellular immune response. This ultimately destroys the myelin. Other factors associated with the development of GBS are listed in Table 46-1.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Obtain a complete health history. Ask the patient to describe GBS symptoms in chronologic order, if possible. Question about the presence of pain, which is common if the patient has **paresthesias** (unpleasant sensations such as burning, stinging, and prickly feeling).

Manifestations of GBS depend on the degree of weakness and the progression of symptoms. Although features vary, most people report a sudden onset of muscle weakness and pain (Chart 46-1). Typically, the disease does not affect level of consciousness, cerebral function, or pupillary constriction or dilation. The clinical variations of GBS reflect the areas of earliest or most severe involvement (Table 46-2).

With any of the variants, *cranial nerve* involvement most often affects the facial nerve (cranial nerve VII). Assess the

TABLE 46-1 FACTORS ASSOCIATED WITH DEVELOPMENT OF GUILLAIN-BARRÉ SYNDROME

• Acute illness • Gastrointestinal illness • <i>Campylobacter jejuni</i> bacteria • Human immune deficiency virus infection • <i>Mycoplasma pneumoniae</i> • Surgery • Upper respiratory infection • Virus • Cytomegalovirus • Epstein-Barr virus • Varicella-zoster virus	• Vaccination • Flu • Group A <i>Streptococcus</i> • Rabies • Drugs • Captopril • Danazol • Penicillamine • Systemic lupus erythematosus • Hodgkin's disease
--	---

CHART 46-1 KEY FEATURES

Guillain-Barré Syndrome

Motor Manifestations

- Ascending symmetric muscle weakness → flaccid paralysis without muscle atrophy
- Decreased or absent deep tendon reflexes (DTRs)
- Respiratory compromise (dyspnea, diminished breath sounds, decreased tidal volume and vital capacity) and respiratory failure
- Loss of bowel and bladder control (less common)
- Ataxia

Sensory Manifestations

- Paresthesias
- Pain (cramping)

Cranial Nerve Manifestations

- Facial weakness
- Dysphagia
- Diplopia
- Difficulty speaking

Autonomic Manifestations

- Labile blood pressure
- Cardiac dysrhythmias
- Tachycardia

TABLE 46-2 CLINICAL VARIANTS OF GUILLAIN-BARRÉ SYNDROME

Ascending GBS

- Most common clinical pattern.
- Weakness, paresthesias, and leg pain begin in the lower extremities and progress upward to include the trunk and arms or affect the cranial nerves.
- Symptoms of an ascending flaccidity or weakness that evolves over hours to several days (1 to 10 days).
- Mild paresis to total quadriplegia.
- Some degree of respiratory compromise.
- Deep tendon reflexes are absent in limbs that become paralyzed.

Pure Motor GBS

- Identical to the ascending variant except sensory manifestations are absent and the patient is generally in much less pain.

Descending GBS

- Initially experiences weakness of the face or **bulbar** muscles of the jaw, the sternocleidomastoid muscles (head rotators), and the muscles of the tongue, pharynx, and larynx.
- Weakness progresses downward to involve the limbs.
- May quickly affect the respiratory function:
 - Breathlessness during speech
 - Shallow respirations
 - Dyspnea
 - Decreased tidal volume
- Often includes **ophthalmoplegia** (paralysis or weakness of the eye muscles), causing diplopia.
- If the papillary response to light is affected, functional blindness may result.
- Numbness is more common in the hands than in the feet.
- Deep tendon reflexes are decreased or absent.

Miller Fisher Variant

- A rare polyneuropathy.
- Triad of ophthalmoplegia, areflexia (absence of reflexes), and severe ataxia (defective muscle coordination).
- Motor strength and sensory function are normal.
- Pupillary response to light is occasionally affected by the ophthalmoplegia, which results in functional blindness.

patient's ability to smile, frown, whistle, or drink from a straw. In addition to monitoring the functions of cranial nerve VII, assess the patient for dysphagia (difficulty swallowing). Less frequently affected cranial nerves include the glossopharyngeal (IX), vagus (X), accessory (XI), and hypoglossal (XII) nerves. The patient's inability to cough, gag, or swallow results from the involvement of cranial nerves IX and X. Monitor the patient closely for varying blood pressure (hypertensive and hypotensive episodes or orthostatic hypotension), bradycardia, heart block, and, possibly, asystole. These symptoms are part of *autonomic dysfunction*, which is linked to vagus nerve (X) deficit. Assess cranial nerve XI (accessory) by asking the patient to shrug the shoulders. Hypoglossal nerve (XII) deficit is evidenced by an inability to stick the tongue out straight.

In addition to determining the usual roles and responsibilities, occupation, motivation, and available support systems, assess the patient's ability to cope with this devastating illness and the accompanying fear and anxiety. In general, GBS is self-limiting and the paralysis is temporary. It is not unusual for the patient to have depression throughout the recovery period, however, due to a feeling of powerlessness.

Although no single clinical or laboratory finding confirms the diagnosis of GBS, the health care provider may perform a lumbar puncture (LP) to evaluate *cerebrospinal fluid (CSF)*. An increase in CSF protein level often occurs due to the release of plasma proteins from inflammation, degeneration, and damage to nerve roots. However, high protein levels may not occur until after 1 to 2 weeks of illness, reaching a peak in 4 to 6 weeks. The CSF lymphocyte count is normal.

Peripheral blood tests may show a moderate *leukocytosis* early in the illness. The number of leukocytes rapidly returns to normal if there are no complications or concurrent illness.

Electrophysiologic studies (EPSs) demonstrate demyelinating neuropathy. The degree of abnormality found on testing does not always correlate with clinical severity. Within 3 weeks of symptoms, nerve conduction velocities are depressed. In some cases, denervated potentials (fibrillations) develop later in the illness. Electromyographic (EMG) findings, which reflect peripheral nerve function, are normal early in the illness. Electrophysiologic changes appear only after denervation of muscle has been present for 4 weeks or longer. Nerve conduction velocity (NCV) testing is performed with the EMG. Nerve damage or disease may still exist despite normal NCV results. These tests are described in Chapter 43.

A magnetic resonance imaging (MRI) or computed tomography (CT) scan may be requested to rule out other causes of motor weakness. Respiratory function is often compromised in patients with GBS. Therefore vital capacity may be decreased and arterial blood gas (ABG) values may be abnormal (decreased partial pressure of arterial oxygen [P_{aO_2}], increased partial pressure of arterial carbon dioxide [P_{aCO_2}], or increased pH).

INTERVENTIONS**Managing Drug Therapy and Plasmapheresis**

The health care provider follows the most recent best practice guidelines from the [American Academy of Neurology \(2011\)](#) for the treatment of GBS. These include:

- Treat with either plasma exchange (PE, also known as *plasmapheresis*) or immunoglobulin. There is no benefit to combine these treatments.
- Implement PE for non-ambulatory adult patients who seek treatment within 4 weeks of the development of symptoms. It is also recommended for ambulatory patients seen within 2 weeks of onset of symptoms.
- Use IV immunoglobulin (IVIG) for ambulatory patients who seek treatment within 2 weeks of onset of symptoms.
- Do not use corticosteroids unless medically necessary to treat other diseases.

Cerebrospinal fluid filtration (CSFF), also called *liquorpheresis*, has been a controversial new treatment option and lacking strong evidence for successfully managing Guillain-Barré syndrome. This procedure involves filtering out immunoglobulins and inflammatory mediators, such as cytokines.

Plasmapheresis removes the circulating antibodies thought to be responsible for the disease. In this procedure, plasma is selectively separated from whole blood. The blood cells are returned to the patient without the plasma. Plasma usually replaces itself, or the patient is transfused with colloid substitute such as albumin. Fresh frozen plasma is

CHART 46-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preventing and Managing Complications of Plasmapheresis

COMPLICATION	NURSING INTERVENTIONS
Trauma or infection at vascular access site	Keep the site clean and dry. Monitor the site for redness, swelling, drainage, or other signs of infection.
Hypovolemia with resultant hypotension, tachycardia, dizziness, and diaphoresis	Monitor fluid and electrolyte status and vital signs. Administer fluids as prescribed. Provide an explanation of side effects, and reassure the patient.
Hypokalemia and hypocalcemia	Monitor fluid and electrolyte balance. Administer replacement electrolytes as prescribed. Observe for cardiac dysrhythmias.
Temporary circumoral and distal extremity paresthesias, muscle twitching, nausea, and vomiting related to administration of citrated plasma	Add calcium gluconate or calcium chloride to exchange fluids as prescribed. Provide explanations, comfort measures, and reassurance.

generally not used because of the associated risk for infection and allergic pulmonary edema. Plasmapheresis should be done within several days after the onset of the illness, although some patients benefit up to 30 days after the onset of symptoms. The patient usually receives three to four treatments, 1 to 2 days apart. Some patients may require a second round of treatment if they deteriorate after the first plasmapheresis.

Nursing interventions for the patient undergoing plasmapheresis include providing information and reassurance, weighing the patient before and after the procedure, and properly caring for the shunt, if used.

! NURSING SAFETY PRIORITY

Action Alert

If a shunt is used for plasmapheresis, be sure to:

- Check shunt patency
 - Assess for bruits every 2 to 4 hours
 - Keep double bulldog clamps at the bedside
 - Observe the puncture site for bleeding or ecchymosis (bruising)
- Observe for signs of complications throughout the procedure (Chart 46-2).

IVIg has been shown to be as effective as plasmapheresis. It is safer and immediately available. Side effects of immunoglobulin therapy range from minor annoyances (e.g., chills, mild fever, myalgia, headache) to major complications (e.g., anaphylaxis, aseptic meningitis, retinal necrosis, acute renal failure). A serum IgA is drawn before administration of the medication. Infuse IVIg slowly when it is started. Observe for side and adverse effects, and report their occurrence to the health care provider. The rate of administration can be increased based on the patient's tolerance and on agency protocol.

Managing the Airway and Monitoring Respiratory Status

The priority nursing intervention of *airway management* is to promote airway patency and gas exchange. Elevate the head of the bed to at least 45 degrees or higher as determined by the patient's response and level of dyspnea. The need for suctioning the patient is based on assessment data. During suctioning, the patient is at risk for vagal nerve stimulation that could lead to bradycardia and cardiac arrest. Monitor the color, consistency, and amount of secretions obtained. Chest physiotherapy, often performed by the respiratory therapist (RT), and frequent position changes are combined with breathing exercises (coughing and deep breathing) to prevent pneumonia and atelectasis. Encourage the patient to use the incentive spirometer to expand the lungs every few hours. Oxygen may be administered by nasal cannula at a flow rate prescribed by the health care provider.

! NURSING SAFETY PRIORITY

Action Alert

In the initial phase of Guillain-Barré syndrome, monitor the patient closely (usually in a critical care unit) for signs of respiratory distress, such as dyspnea, air hunger, adventitious breath sounds, decreased oxygen saturation, and cyanosis. In addition, assess respiratory rate, rhythm, and depth every 1 to 2 hours. In collaboration with the respiratory therapist (RT), check vital capacity every 2 to 4 hours and auscultate the lungs at 4-hour intervals. Monitor the patient's ability to cough and swallow for any change. Assess cognitive status, especially in older adults; a decline often indicates hypoxia.

Monitor ABG values or end-tidal carbon dioxide frequently for acid-base abnormalities; pulse oximetry reveals decreasing oxygen saturation. A decrease in vital capacity to less than 15 to 20 mL/kg (or less than two thirds of the patient's normal) and the inability to clear secretions may be indications for elective intubation.

! NURSING SAFETY PRIORITY

Critical Rescue

Keep equipment for performing an endotracheal intubation at the bedside of the patient with Guillain-Barré syndrome, and have a mechanical ventilator readily available in case of respiratory emergency.

Managing Cardiac Dysfunction

Both the sympathetic and parasympathetic systems may be affected. Place the patient on a cardiac monitor because of the risk for dysrhythmias. Monitor vital signs closely. Hypertension is treated with a beta blocker or nitroprusside (Nitro-press). Hypotension is treated with IV fluids and placing the patient in a supine position unless he or she is in extreme respiratory distress. Atropine may be prescribed to treat bradycardia.

Improving Mobility and Preventing Complications of Immobility

Collaborate with the patient, family, physical and occupational therapists (PT/OT), speech-language pathologist (SLP), and dietitian to develop interventions that prevent complications of immobility and to address deficits in self-care. Assess the patient's motor (muscle) function every 2 to 4 hours as part

of the neurologic assessment. The interventions prescribed for mobility and self-management and to prevent complications depend on the degree of motor deficit. The PT and OT provide assistive devices and instructions for their use.

To ensure safety, assist the patient with ambulation, transfers from bed to chair, position changes, and maintenance of proper body alignment until he or she is able to perform these activities independently. Encourage maximum independence. Perform active or passive range-of-motion (ROM) exercises every 2 to 4 hours, or delegate this activity to unlicensed assistive personnel (UAP) with supervision. Teach family members these techniques. (See Chapter 8 for detailed discussion of ways to improve physical mobility and self-care, as well as ways to prevent immobility consequences.) Monitor the patient's responses, including fatigue level. Provide adequate rest periods between activities and therapy sessions.

Decreased gastric motility, dysphagia, and depression can cause malnutrition. Collaborate with the dietitian to develop an individualized plan. The patient may require little assistance with feeding or may be totally dependent. If he or she cannot safely swallow food or liquids, enteral nutrition via feeding tube is prescribed. Weigh the patient three times a week, and monitor serum prealbumin each week.

Malnutrition places patients at risk for pressure ulcers, especially when they are immobile. Therefore pay special attention to skin care, including interventions to prevent skin breakdown. Instruct UAP to turn the patient a minimum of every 2 hours. Assess the skin for any areas of redness that may lead to pressure ulcers. If the bed does not have a pressure-reducing mattress, use a mattress overlay to help prevent skin breakdown. Document changes in the patient's skin condition every 8 to 12 hours while in the acute care setting and at least daily in a transitional care or rehabilitation setting. If an ulcer develops, implement aggressive interventions to manage the wound. Chapters 8 and 27 discuss pressure ulcer care in detail.

Because pulmonary emboli and deep vein thromboses are common complications of immobility, the health care provider may prescribe prophylactic anticoagulant therapy, such as subcutaneous heparin or Lovenox. Antiembolism stockings and sequential compression stockings may be used to promote venous return. Be sure that stockings are removed at least once every 24 hours for 15 to 30 minutes. Other prevention measures are determined by agency policy or health care provider preference. Chapter 8 describes additional interventions to prevent complications of immobility and promote self-care.

Managing Pain

Assess the severity and nature of the patient's pain, which is often worse at night. The patient may have paresthesia or hyperesthesia (extreme sensitivity to touch), deep muscle aches, and muscle stiffness. The typical pain experienced is often not relieved by drugs other than opiates, which can be

administered via a patient-controlled analgesia (PCA) pump or continuous IV drip. Other drugs that are given include gabapentin (Neurontin) or tricyclic antidepressants.

Other pain control measures include frequent repositioning, massage, ice, heat, relaxation techniques, guided imagery, hypnosis, and distractions (e.g., music, visitors). Chapter 5 discusses these modalities and other pain relief measures in detail.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is admitted to the critical care unit with possible Guillain-Barré syndrome. Which assessment is the most important for this client?

- A. Nutritional status assessment
- B. Nervous system assessment
- C. Mental status assessment
- D. Respiratory system assessment

Promoting Communication

The patient may have difficulty communicating because the muscles required for the production of speech are weak, or he or she may be mechanically ventilated because the respiratory muscles are paralyzed. In either case, collaborate with the speech-language pathologist to develop a communication system. A simple technique involves eye blinking or moving a finger to indicate “yes” and “no.” A communication board or flash cards can be used with the letters of the alphabet or a list of common requests, such as the need to be repositioned or the need for pain medication. Computer or personal digital assistant (PDA) technology may also be used, depending on muscle function. Both the staff and the visitors must know how the patient's communication system operates.

Providing Psychosocial Support

Teach the patient and family about the illness, and explain all diagnostic tests and treatments. Assess the patient and family for verbal and nonverbal behaviors that indicate powerlessness, anxiety, fear, and isolation (Simmons, 2010). Encourage the patient to verbalize feelings about the illness and its effects, if possible, while fostering hope. Assess previous decision-making patterns, roles, and responsibilities. To help identify personal factors that influence coping ability, ask the patient and/or family to describe their usual lifestyles and the situations in which they coped effectively. Sleep disturbances related to pain and altered autonomic function may affect the patient's sleep-wake cycle. Allow for regularly scheduled rest periods (Simmons, 2010).

Refer patients who need further psychosocial support to the social worker, certified hospital chaplain or appropriate spiritual resource, and local support groups. If necessary, obtain a psychological consultation for further evaluation and intervention.

Community-Based Care

The severity and course of Guillain-Barré syndrome (GBS) are extremely variable, which makes the prognosis difficult to predict. The most likely residual deficits at discharge are related to motor status and mobility, self-management, and possibly sensory alteration and disturbed self-concept. For patients who have total quadriparesis (weakness in all four extremities) or respiratory paralysis, the course of the

! NURSING SAFETY PRIORITY

Drug Alert

Older adults should not receive tricyclic drugs because they cause serious side effects such as urinary retention and blurred vision. Document the patient's response to pain medication, and notify the health care provider if pain relief is not sufficient.

rehabilitation phase is even more variable and may require weeks to years. The expected outcome of the recovery phase is to move from dependence to independence, if possible.

Planning for discharge begins on admission. The patient may be discharged to home or to a rehabilitation unit. In collaboration with the discharge planner or case manager (CM), the nurse makes appropriate referrals to a rehabilitation setting, home care agency, and/or community agencies for assistance in the home setting after discharge.

Include a family member in the education process throughout the patient's hospitalization and in the discharge process. Provide them with both oral and written instructions to improve mobility, use adaptive-assistive devices, and prevent skin breakdown.

If the patient is discharged to home while still needing assistive devices, the CM in collaboration with the interdisciplinary health care team makes certain that the necessary equipment has been delivered after evaluating the home setting. Home care management for patients with GBS is similar to that for those who have had a stroke or spinal cord injury, depending on the nature of the neurologic deficit.

Self-help and support groups for patients with chronic illness are common. Refer the patient and family to these groups, if indicated. For example, the Guillain-Barré Syndrome Foundation International (www.gbs-cidp.org) provides resources and information for patients and their families. The psychosocial adjustment needed may be minimal or dramatic, depending on the patient's residual deficit, age, gender, usual roles and responsibilities, usual coping strategies, available support systems, and occupation. Help the patient identify other support systems, such as church members, friends, or spiritual resources.

MYASTHENIA GRAVIS

Pathophysiology

Myasthenia gravis (MG) is an acquired autoimmune disease characterized by fatigue and weakness primarily in muscles innervated by the cranial nerves, as well as in skeletal and respiratory muscles. This autoimmune disease of the neuromuscular junction may take many forms—from mild disturbances of the ocular muscles to a rapidly developing, generalized weakness that may lead to death from respiratory failure. It has remissions and exacerbations (worsening or “flare-ups”). Although MG can present at any age, it is less commonly seen in the United States than Guillain-Barré syndrome. The incidence is equal between men and women.

MG is caused by an autoantibody attack on the acetylcholine receptors (AChRs) in the muscle end plate membranes. As a result, nerve impulses are not transmitted to the skeletal muscle at the neuromuscular junction and the muscles cannot contract.

Although the disease is not hereditary, there is a small familial incidence. Evidence also suggests a relationship between MG and hyperplasia (overgrowth) of the thymus gland. The thymus gland is often abnormal. **Thymoma** (encapsulated thymus gland tumor) occurs in a few cases, but most of the remaining cases show hyperplasia of the thymus. There is also a very strong association between MG and hyperthyroidism. D-penicillamine, interferon-alpha, and

bone marrow transplantation have been associated with drug-induced (iatrogenic) autoimmune MG.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Although the onset of MG is usually insidious (slow), some instances of fairly rapid development have been caused by infection, pregnancy, or anesthesia. Ask about any history of these events. A temporary increase in weakness may be noted after vaccination, menstruation, and exposure to extremes in environmental temperature.

In addition to the biographic data and history, ask the patient if he or she noticed the rapid onset of fatigue. Note reports of muscle weakness that increases on exertion or as the day wears on and improves with rest. Ask the patient to describe his or her symptoms, specifically noting the affected muscle groups and any limitation or inability in performing ADLs.

Additional areas of inquiry include any history of **ptosis** (drooping eyelids), **diplopia** (double vision), or **dysphagia** (difficulty chewing or swallowing) and the type of diet best tolerated. Assess the patient about a history of respiratory difficulty, choking, or voice weakness. Other areas of assessment include asking about any difficulty holding up the head, brushing teeth, combing hair, or shaving. Inquiry is made about the presence of paresthesias or aching in weakened muscles. Finally, ask about a history of thymus gland tumor.

The most common symptoms are related to involvement of the levator palpebrae or extraocular muscles (**Chart 46-3**). Assess for ptosis, diplopia, and weak or incomplete eye closure. These symptoms may last only a few days at the onset and then resolve, only to return weeks or months later. Pupillary responses to light and accommodation are usually normal.

For most patients, the muscles of facial expression, chewing, and speech are affected (**bulbar** involvement). Note the patient's smile, which may be transformed into a snarl. The jaw may hang so that the patient must prop it up with the hand. Chewing and swallowing difficulties, choking, and regurgitation of fluids through the nose may lead to considerable weight loss. Ask about the patient's nutritional intake and any recent weight loss. He or she may have more

CHART 46-3 KEY FEATURES

Myasthenia Gravis

Motor Manifestations

- Progressive muscle weakness (proximal) that usually improves with rest
- Poor posture
- Ocular palsies
- Ptosis
- Weak or incomplete eye closure
- Diplopia
- Respiratory compromise

- Loss of bowel and bladder control
- Fatigue

Sensory Manifestations

- Muscle aching
- Paresthesias
- Decreased sense of smell and taste

difficulty eating after talking. After extended conversations, the voice may become weaker or exhibit a nasal twang. In some patients, the tongue has fissures (ulcers).

Less often involved are the muscles of the shoulders, the flexors of the neck, and the hip flexors. Because limb weakness is more often *proximal* (closer to the body), the patient may have difficulty climbing stairs, lifting heavy objects, or raising the arms overhead. Neck weakness may be mild or severe enough to cause difficulty in holding the head erect. Among the trunk muscles, the erector spinae are most commonly affected. This results in difficulty maintaining a sitting or walking posture.

In the most advanced cases of MG, all muscles are weakened, including those associated with respiratory function and the control of bladder and bowel function. In these severe cases, ask about bowel and bladder function. Assess respiratory function frequently.

Muscle atrophy, although rarely severe, occurs in a small percentage of patients with myasthenia gravis (MG). The tendon reflexes should be assessed, but they are not often affected. Assess for pain, although this is seldom a major concern. Some patients report that their weakened muscles ache. If present, paresthesias (painful tingling sensations) affecting the muscles of the face, hands, and thighs are not associated with any loss of sensation. Lost or decreased sensations of smell and taste have been reported. Consciousness is not altered.

In **Eaton-Lambert syndrome**, a form of myasthenia often seen with small cell carcinoma of the lung, the muscles of the trunk and the pelvic and shoulder girdles are most commonly affected. Although weakness increases after exertion, muscle strength may temporarily increase during the first few contractions, followed by rapid decline. Diagnosis is confirmed by electromyography (EMG). Management differs somewhat from that of other types of MG. Treatment includes removing the tumor, managing the cancer, and administering drug therapy to release acetylcholine (ACh). Additional therapies may include plasmapheresis and immunosuppressive therapy (discussed later).

Diagnostic Assessment

Because the incidence of MG is rare, diagnosis may be delayed or missed. An experienced clinician can diagnose the disease from the history and physical examination findings. MG may be immediately confirmed by the patient's response to cholinergic drugs. A standard series of laboratory studies is usually performed for patients with known or suspected MG. **Thyroid function** should be tested because **thyrotoxicosis** (excessive thyroid hormone) is present in a small number of myasthenic patients. *Serum protein electrophoresis* evaluates the patient for immunologic disorders. Immunologic-based diseases, such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis, are associated with the disease.

Testing for *acetylcholine receptor (AChR) antibodies* has become an important diagnostic criterion, because they are elevated in most patients with MG. A positive antibody test result confirms the diagnosis, but a negative finding does not rule out the disease.

Some patients with MG have a thymoma, and therefore patients are assessed for this condition. The thymus, an H-shaped gland located in the upper mediastinum beneath the sternum, is one organ in which AChR antibodies are

formed. Although a thymoma can often be seen on routine frontal and lateral chest x-rays, a *CT scan* is also done.

Repetitive Nerve Stimulation. The most common electrodiagnostic test performed to detect myasthenia gravis (MG) is repetitive nerve stimulation (RNS) of proximal nerves. Each nerve studied is electrically stimulated six to ten times at 2 or 3 Hertz. The compound muscle action potential (CMAP) is recorded with surface electrodes over muscle. In MG, there is a progressive decline in CMAP amplitude (force, or strength) with the first 4 or 5 stimuli. This test diagnoses most cases of generalized MG but far fewer cases of ocular MG.

Electromyography. An older but relatively common electrodiagnostic test performed by the physician or technician is electromyography (EMG). Although electrical testing of the normal neuromuscular junction produces no change in the amplitude of muscle contraction, the amplitude of the muscle's response diminishes with progressive stimulation. A decrease in amplitude of more than 10% between the first and fifth responses generally indicates the defective neuromuscular transmission characteristic of, but not unique to, MG. Several muscles may be tested to increase the likelihood of detecting an abnormality. Testing may be performed after exercise or exposure of the muscle to curare or to ischemia.

Single-fiber EMG (SFEMG) is a newer and most sensitive form of electromyography in detecting defects of neuromuscular transmission. This test compares the stability of the firing of one muscle fiber with that of another fiber innervated by the same motor neuron. The time interval between the two firings normally shows a minor degree of variability, called *jitter*. Defective transmission increases jitter or actually blocks successive discharges. This test can diagnose almost all cases of generalized and ocular MG.

Tensilon Testing. Pharmacologic tests with the cholinesterase inhibitors *edrophonium chloride* (*Tensilon*) and *neostigmine bromide* (*Prostigmin*) may be performed. This older test is often referred to as a *Tensilon challenge test*. Tensilon is used most often for testing because of its rapid onset and brief duration of action. This drug inhibits the breakdown of ACh at the postsynaptic membrane, which increases the availability of ACh for excitation of postsynaptic receptors. To perform the test, the physician first estimates the strength of cranial muscles. Initially, 2 mg (0.2 mL) is injected IV; if this is tolerated, an additional 8 mg (0.8 mL) is injected after 30 seconds. Within 30 to 60 seconds of the first dose, most myasthenic patients show a marked improvement in muscle tone that lasts 4 to 5 minutes. False-positive test results may be caused by increased muscle effort by the patient. False-negative findings may be seen if the tested muscle is extremely weak or refractory to the drug.

Tensilon testing may be used also to help determine whether increasing weakness in the previously diagnosed myasthenic patient is due to a **cholinergic crisis** (too much cholinesterase inhibitor drugs) or a **myasthenic crisis** (too little cholinesterase inhibitor drugs). In a cholinergic crisis,

! NURSING SAFETY PRIORITY

Drug Alert

The Tensilon test can cause ventricular fibrillation and cardiac arrest, but these reactions rarely occur. Be sure that atropine sulfate, the antidote for Tensilon, is available in case these complications occur.

muscle tone does not improve after giving Tensilon. Instead, weakness may actually increase and **fasciculations** (muscle twitching) may be seen around the eyes and face.

INTERVENTIONS

The classic presentation of MG is muscle weakness that increases when the patient is fatigued and limits his or her *mobility* and ability to participate in activities. Management for this disease falls into two categories:

- Treatment that affects the symptoms of MG without influencing the actual course of the disease (anticholinesterases or cholinergic drugs)
- Therapeutic efforts for inducing remission, such as the administration of immunosuppressive drugs or corticosteroids, plasmapheresis, and thymectomy (removal of the thymus gland)

Nonsurgical Management

Although not all patients with MG have respiratory compromise, ongoing assessment and maintenance of respiratory function are nursing care priorities.

Providing Respiratory Support. Both myasthenic crisis and cholinergic crisis increase muscle weakness and the patient's risk for respiratory compromise. The diaphragm and intercostal muscles may be affected, which inhibits the patient's ability to maintain adequate ventilation, breathe deeply, and cough effectively. In addition, dysphagia may result in the aspiration of foods, fluids, or saliva, which worsens the respiratory problems. Because of their respiratory muscle involvement, many of these patients have an increased risk for lung infections.

The patient who cannot cough effectively may require oropharyngeal or nasopharyngeal suctioning. If needed, teach the assisted-cough technique, similar to that used by patients who are quadriplegic. Collaborate with the respiratory therapist (RT) to provide chest physiotherapy consisting of postural drainage, percussion, and vibration to mobilize secretions.

! NURSING SAFETY PRIORITY

Critical Rescue

Keep a manual resuscitation (breathing) bag (e.g., Ambu), equipment for oxygen administration, and endotracheal intubation equipment at the bedside of the patient with myasthenia gravis in case of respiratory distress!

Because breathing difficulty or the inability to breathe easily is frightening, be aware of the patient's mental and emotional status during periods of respiratory compromise. Monitor his or her response to drug therapy for muscle weakness. Monitor for pulmonary congestion that can lead to respiratory complications like pneumonia and atelectasis.

As an alternative to mechanical ventilation, bi-level positive airway pressure (BiPAP) should be tried first in patients with acute respiratory failure from MG crisis while awaiting improvement from IV immunoglobulin (IVIG) therapy or plasma exchange. Repeat blood gas measurements and clinical assessment after using the device for a few hours are used to determine its effects.

Promoting Mobility. Assess the patient's muscle strength before and after periods of activity. Provide assistance as

necessary to prevent the patient from becoming fatigued. Schedule him or her for tests, treatments, and other activities early in the day or during the energy peaks after giving the prescribed drugs. Assist the patient in planning the periods of rest necessary for avoiding excess fatigue.

During periods of maximum weakness, provide assistance for ambulation, transfers from bed to chair or toilet/commode, position changes, and maintenance of body alignment. Active or passive ROM exercises are performed every 2 to 4 hours with assistance of the nurse, UAP, or family. Assess bony prominences for skin breakdown at least every 2 hours. Teach family members how to perform this skill. Pressure-reducing devices or mattresses are used to help prevent pressure ulcers. Collaborate with the physical and occupational therapists to develop a program for the patient to assist with mobility, self-care, and energy conservation techniques. **Chapter 8** discusses other interventions for preventing complications of immobility.

Administering Drug Therapy. Two groups of drugs are typically prescribed for the treatment of myasthenia gravis (MG): anticholinesterases and immunosuppressants. Be sure to give these drugs on time to maintain blood levels and thus improve muscle strength. Monitor and document the patient's response to drug therapy. Provide information for the patient and the family about the indications for, effectiveness of, and side effects of the drugs used in the treatment of MG.

Cholinesterase Inhibitor Drugs. Cholinesterase (ChE) inhibitor drugs are the first-line management of MG. These drugs are also referred to as *anticholinesterase drugs* or *anti-myasthenics*. They enhance neuromuscular impulse transmission by preventing the decrease of ACh by the enzyme ChE. This increases the response of the muscles to nerve impulses and improves muscle strength. The ChE inhibitor drug of choice is pyridostigmine (Mestinon, Regonol). Expect day-to-day variations in dosage depending on the patient's changing symptoms.

Administer ChE inhibitors with a small amount of food to help alleviate GI side effects.

! NURSING SAFETY PRIORITY

Drug Alert

Instruct the patient to eat meals 45 minutes to 1 hour after taking ChE inhibitors to avoid aspiration. This is especially important if the patient has bulbar involvement. Drugs containing magnesium, morphine or its derivatives, curare, quinine, quinidine, procainamide, or hypnotics or sedatives should be avoided because they may increase the patient's weakness. Antibiotics such as neomycin and certain tetracyclines impair transmitter release and also increase myasthenic symptoms.

A potential adverse effect of ChE inhibitors is cholinergic crisis. Sudden increases in weakness and the inability to clear secretions, swallow, or breathe adequately indicate that the patient is experiencing crisis. Teach the patient and family to monitor for these two types of crises:

1. Myasthenic crisis—an exacerbation (flare-up or worsening) of the myasthenic symptoms caused by not enough anticholinesterase drugs
2. Cholinergic crisis—an acute exacerbation of muscle weakness caused by too many anticholinesterase drugs

Because myasthenic and cholinergic crises have many common characteristics, the type of crisis the patient is

TABLE 46-3 CHARACTERISTICS OF MYASTHENIC AND CHOLINERGIC CRISES

MYASTHENIC CRISIS	CHOLINERGIC CRISIS	MIXED CRISIS
Increased pulse and respiration	Nausea	Apprehension
Rise in blood pressure	Vomiting	Restlessness
Anoxia	Diarrhea	Dyspnea
Cyanosis	Abdominal cramps	Dysphagia (difficult swallowing)
Bowel and bladder incontinence	Blurred vision	Dysarthria (painful joints)
Decreased urine output	Pallor	Increased lacrimation (tearing)
Absence of cough and swallow reflex	Facial muscle twitching	Increased salivation
	Pupillary miosis	Diaphoresis
	Hypotension	Generalized weakness

experiencing must be identified for effective treatment to be provided (Table 46-3). Monitor carefully for early detection of these emergencies if the patient is in a health care setting.

Emergency Care: Myasthenic Crisis. Myasthenic crisis is often caused by some type of infection. For other patients, increasing muscle weakness leads to an overdose of anticholinesterase drugs. As a result, the patient may experience a *mixed* crisis. The Tensilon test (described on p. 992), although not always conclusive, is an important procedure for differentiation. *Tensilon produces a temporary improvement in myasthenic crisis but worsening or no improvement of symptoms in cholinergic crisis.*

The priority for nursing management of the patient in myasthenic crisis is maintaining adequate respiratory function. The acutely ill patient may need intensive nursing care for monitoring and maintenance of body functions. He or she may require mechanical ventilation. Cholinesterase-inhibiting drugs are withheld because they increase respiratory secretions and are usually ineffective for the first few days after the crisis begins. Drug therapy is restarted gradually and at lower dosages.

Emergency Care: Cholinergic Crisis. In *cholinergic* crisis, do not give anticholinesterase drugs while the patient is maintained with mechanical ventilation. Atropine 1 mg IV may be given and repeated, if necessary. When atropine is prescribed, observe the patient carefully. Secretions can be thickened by the drug, which causes more difficulty with airway clearance and possibly the development of mucous plugs. Unless complications such as pneumonia or aspiration develop, the patient in crisis improves rapidly after the appropriate drugs have been given. Continue to provide assistance as necessary because he or she tires easily after minimal exertion.

Immunosuppression. Immunosuppression may be accomplished with the use of corticosteroids or chemotherapeutic agents. Prednisone is given initially to produce remission and to control and improve symptoms. The drug is tapered over a period of weeks to months. Some patients may need continuous low-dose therapy because of exacerbations of symptoms. For ocular MG, corticosteroid treatment that does not cause significant systemic complications may significantly reduce the prevalence of generalized myasthenia gravis after 2 years on the drug. IV immunoglobulins (IVIGs) may also be used for acute disease management or as a long-term option for disease refractory to other treatment.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client with myasthenia gravis has been prescribed to take pyridostigmine (Mestinon). What health teaching will the nurse include related to this drug? **Select all that apply.**

- A. "Watch for signs and symptoms of myasthenic crisis."
- B. "Take the drug about an hour before eating a meal."
- C. "Take the same dose of medication every day."
- D. "Take the drug with food to prevent nausea."
- E. "Do not take sedatives or sleeping pills while on this drug."

Assisting with Plasmapheresis. **Plasmapheresis** is a method by which antibodies are removed from the plasma to decrease symptoms. This is used as short-term management of an exacerbation. Six exchanges occur over a 2-week period with follow-up exchanges weekly or monthly as needed. This procedure is usually done on an ambulatory care basis. Nursing management of the patient undergoing plasmapheresis is presented in the earlier discussion of Guillain-Barré syndrome, p. 988.

Other Interventions. Generalized weakness and fatigue affect the patient's ability to participate in ADLs. Impaired fine motor control and shoulder weakness, which results in difficulty raising the arms, can compound the problem. Self-care deficits may be complete or partial depending on the severity of the illness, the patient's response to drugs, and his or her ability to tolerate activity without excessive fatigue.

To establish limitations, assess the patient's ability to perform ADLs. Although he or she is encouraged to perform activities as independently as possible, assistance is provided as needed to avoid frustration and fatigue. *For maximizing independence and making attempts at self-management successful, plan activities to follow the administration of medication.* Monitor and document the patient's response to or tolerance of activity, providing alternating periods of activity and rest. *Rest is critical because increased fatigue can precipitate a crisis.* In addition, occupational and physical therapists evaluate him or her for assistive-adaptive devices. In collaboration with the nurse, they teach the patient and family energy conservation techniques and ideas for making work and self-management easier after discharge from the hospital.

Weakness of the speech and facial muscles often results in dysarthric (slurred) and nasal speech. Thus it may be difficult for myasthenic patients to make their speech understood by others.

In collaboration with the speech-language pathologist (SLP), determine the patient's ability to communicate. Instruct the patient to speak slowly while attempting to lip-read. Repeat what the patient says to check that it is correct. Questions that can be answered with "yes" or "no" or by gestures may be used along with other communication systems such as eye blinking, notebook and pencil, computer, PDA, and picture, letter, or word boards.

The patient with myasthenia gravis (MG) may have difficulty maintaining an adequate intake of food and fluid because the muscles needed for chewing and swallowing become weakened and tire easily. In collaboration with the dietitian, occupational therapist, and speech-language pathologist, evaluate the patient's nutritional status and his or her ability to receive adequate oral nutrition. Small,

CHART 46-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Improving Nutrition in Patients with Myasthenia Gravis

- Assess the patient's gag reflex and ability to chew and swallow.
- Provide frequent oral hygiene as needed.
- Collaborate with the dietitian, speech-language pathologist, and occupational therapist to plan and implement meals that the patient can eat and enjoy.
- Offer small, frequent meals.
- Cut food into small bites, and encourage the patient to eat slowly.
- Observe the patient for choking, nasal regurgitation, and aspiration.
- Provide high-calorie snacks or supplements (e.g., puddings).
- Keep the head of the bed elevated during meals and for 30 to 60 minutes after the patient eats.
- Avoid liquids because they can easily cause choking and aspiration; provide a soft diet.
- Monitor food intake carefully.
- Weigh the patient daily.
- Monitor serum prealbumin levels.
- Administer anticholinesterase drugs, as prescribed: 45 to 60 minutes before meals.

frequent meals and high-calorie snacks are often well tolerated. Monitor the effectiveness of the nutrition program by recording the patient's calorie counts, intake and output, serum prealbumin levels, and daily weights (Chart 46-4). If he or she cannot swallow, a feeding tube may be used.

The patient's inability to completely close the eyes may lead to corneal abrasions and further decrease vision and comfort. During the day, apply artificial tears to keep the corneas moist and free from abrasion. A lubricant gel and shield may be applied to the eyes at bedtime to provide more extensive coverage. To help relieve diplopia, cover the eyes with a patch for 2 to 3 hours at a time, one eye at a time. At times, patients tape their eyes shut at night.

Surgical Management

For patients with MG, **thymectomy** (removal of the thymus gland) is usually performed early in the disease. The procedure is not always immediately effective, and it may take several years for remission to occur—if it occurs at all. Those who have surgery within 2 years of the onset of myasthenic symptoms show the most improvement.

Provide routine preoperative care as discussed in Chapter 16. Because there is no way to predict whether remission or improvement will occur, it is important to avoid making promises, but be optimistic. Immediately before surgery, pyridostigmine (Mestinon) may be given with a small amount of water to keep the patient stable during and after surgery. If steroids have been used, they are also given before surgery and are tapered during the postoperative period. Antibiotics are administered immediately before or during the surgery. Plasmapheresis may be used before and after surgery to decrease circulating antibodies more quickly.

One of two surgical approaches may be used: the transcervical incision (minimal access technique) or the sternal split. The *transcervical approach* is becoming more popular because it allows more rapid recovery with less discomfort after surgery, especially if done using the video-assisted thoracoscopic (VATS) technique (Maat, 2008). However, this

procedure is used only for patients who do not have a thymoma. Only a small dressing and an IV line are needed after surgery.

The older *sternal split* procedure is preferred when patients have a thymoma. It allows the surgeon to directly see the mediastinum and areas around the thymus. When thymoma is present, all surrounding involved structures (i.e., the pericardium, the innominate vein, a portion of the superior vena cava, and a portion of the lung) are removed. A single chest tube is placed in the anterior mediastinum. The patient is usually admitted to the critical care unit after surgery. Thymoma should be considered as a potentially malignant tumor requiring prolonged follow-up. The presence of myasthenic weakness can still complicate its management.

Although patients with adequate respiratory function may be extubated immediately after surgery, most require a gradual weaning from the ventilator. Prolonged ventilatory assistance is rare. *After the patient is extubated, pay special attention to pulmonary hygiene.* Suctioning is performed as necessary. Encourage the patient to turn, cough, and breathe deeply and to use incentive spirometry every 2 hours.

! NURSING SAFETY PRIORITY

Critical Rescue

In addition to monitoring respiratory function and providing bronchial hygiene, observe for signs of pneumothorax or hemothorax for the patient having a thymectomy, including:

- Chest pain
- Sudden shortness of breath
- Diminished or delayed chest wall expansion
- Diminished or absent breath sounds
- Restlessness or a change in vital signs (decreasing blood pressure or a weak, rapid pulse)

Provide oxygen to the patient, and raise the head of the bed to at least 45 degrees. Then report any of these signs and symptoms to the surgeon or Rapid Response Team immediately!

For the sternal surgical technique, provide chest tube care (see Chapter 34). Both surgical approaches require sterile technique for wound care. Observe the patient for signs of infection, such as increasing or purulent drainage; redness, warmth, or swelling around the wound; and elevated temperature. Patient and family teaching is needed about follow-up care before discharge from the hospital.

? NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

When caring for a client with myasthenia gravis, which of these nursing activities may be safely delegated to a nursing assistant?

Select all that apply.

- A. Feeding dinner to the client
- B. Teaching the family about drug therapy
- C. Assisting with client communication
- D. Consulting with the physical therapist
- E. Assisting with ambulation
- F. Recording food and fluid intake

Community-Based Care

The patient with myasthenia gravis (MG) may be cared for in a variety of settings, including the home, transitional care, rehabilitation setting, or long-term care facility. The patient

TABLE 46-4 FACTORS PRECIPITATING OR WORSENING MYASTHENIA GRAVIS

- Various drugs, including:
 - Strong cathartics
 - Antidysrhythmics
 - Beta-blocking agents
 - Antibiotics
 - Antirheumatic drugs
 - Antispasmodics
 - Antihistamines
 - Opioids
 - Phenytoin (Dilantin)
 - Antidepressants (tricyclics)
- Rheumatoid arthritis
- Alcohol
- Hormonal changes
- Stress
- Infection
- Seasonal temperature changes
- Heat
- Surgery
- Enemas

discharged from the hospital may be weak and may require the assistance of a family member, home care nurse, physical therapist (PT), occupational therapist (OT), and/or home care aide.

Home Care Management

Patients with MG are often managed at home. They are hospitalized for diagnostic evaluation, myasthenic or cholinergic crisis resulting in respiratory failure, or periods of exacerbation when respiratory function is threatened.

Unless the patient requires assistive devices, little preparation of the home setting is required. In collaboration with physical and occupational therapists, the case manager (CM) and nurse make certain that the necessary equipment has been delivered and properly installed. In addition, they teach the patient and family members how to use the equipment safely. If the patient becomes wheelchair dependent, the discharge planner, CM, or OT checks on any necessary modifications to the home (e.g., the installation of ramps or widening of doorways) that have been completed. The health care team must make sure that all of the patient's continuing care needs can be met wherever he or she is transferred after discharge from the hospital.

Teaching for Self-Management

The more the patient and family know about the disease and the drugs used for treatment, the less likely it is that complications will develop. Encourage the patient and the family to ask questions. Discuss the episodic nature of the disease, including factors that increase the risk for exacerbation, such as infection, stress, surgery, hard physical exercise, sedatives, and enemas or strong cathartics (Table 46-4). Teach the patient the importance of collaborating with the health care team to monitor muscle strength, ability to perform ADLs, and the need to adjust drug therapy.

Stress the importance of lifestyle adaptations such as avoiding heat (e.g., sauna, hot tubs, sunbathing), crowds, overeating, erratic changes in sleep habits, or emotional extremes. Teach the signs of exacerbation, such as increased weakness, increased diplopia, ptosis, and problems with chewing or swallowing. Remind the patient to plan activities to allow for rest periods and to conserve energy.

Provide the drug regimen in a written format that includes the names, purposes, dosages, scheduled dosage times, and side effects of the drugs. Explain that the drugs are normally taken before activities such as eating, participating in sports,

CHART 46-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Helpful Hints for Teaching Patients with Myasthenia Gravis About Drug Therapy

- Keep prescribed drugs and a glass of water at your bedside if you are weak in the morning.
- Wear a watch with an alarm function (or beeper) to remind you to take your drugs.
- Post your drug schedule so others know it.
- Plan strenuous activities, when possible, when the drug peaks.
- Keep an extra supply of drugs in your car or at work. Be sure they are secured.
- Do not take any over-the-counter drugs without checking with your health care provider.

or working. Stress the importance of maintaining therapeutic blood levels by taking the medications on time and as prescribed and not missing or postponing doses (Chart 46-5). In addition, inform the patient of the side effects of anticholinesterase drugs. Advise him or her to avoid drugs such as morphine, curare, quinine, quinidine, procainamide, mycin-type antibiotics, and drugs containing magnesium. In preparing the patient for discharge, explain the signs and symptoms of myasthenic and cholinergic crises and the need to contact the physician or other health care professional whenever either type of crisis is suspected.

! NURSING SAFETY PRIORITY

Action Alert

Because respiratory compromise often occurs in myasthenic patients, encourage family members to learn resuscitation procedures. A manual resuscitation bag, suctioning equipment, and oxygen should be available in the home for patients susceptible to crises. Teach family members in the proper use of equipment.

The episodic nature of MG, the potential or actual loss of independence, and body image changes (e.g., the inability to smile) affect the patient's adjustment. During discharge planning, the CM considers factors such as age, gender, usual roles and responsibilities, available support systems, occupation, and financial status. Because the patient's and family's need for psychosocial adjustment may range from minimal to dramatic, the CM remains sensitive to their needs and provides information and support. Encourage family members or significant others to discuss their feelings with one another.

Health Care Resources

In collaboration with the health care provider, patient, and family, the staff nurse or CM may initiate referrals to home care agencies and to local self-help groups for people who have chronic illnesses and for their families. The Myasthenia Gravis Foundation (www.myasthenia.org) has education and research programs and provides assistance with financial aid and community resources. Support groups are also available. Teach the patient the importance of obtaining and wearing a medical alert (MedicAlert) bracelet or necklace and to carry a medical alert identification card at all times.

FIG. 46-1 Distribution of selected peripheral nerves in the body. The nerves most commonly affected by trauma are highlighted in bold type.

PERIPHERAL NERVE TRAUMA

Pathophysiology

The peripheral nerves are subject to injuries associated with mechanical or vehicular accidents, sports, the injection of particular drugs, military conflicts or wars, and acts of violence (e.g., knife or gunshot wounds). Specific mechanisms of injury include:

- Partial or complete severance of a nerve or nerves
- Contusion, stretching, constriction, or compression of a nerve or nerves
- Ischemia to nerves
- Electrical, thermal, or radiation injury to one or more nerves

Most commonly affected are the median, ulnar, and radial nerves of the arms and the peroneal, femoral, and sciatic nerves of the legs (Fig. 46-1).

After a nerve is cut or damaged, the nerve distal to the injury degenerates and retracts within 24 hours. Motor and sensory dysfunction below the injury coincide with the loss of electrical excitability as the nerve fibers degenerate. Recovery occurs

as Schwann cells of the neurilemma regenerate from both the proximal and distal stumps. Dividing mitotically, these cells form neurilemmal cords, which act as guidelines for the regenerating axon. Tiny unmyelinated sprouts are generated at the proximal axon and grow 1 to 4 mm each day. Some can cross the transected gap through guidance by the neurilemma to find their way to the distal stump. The better aligned the union, the more normal the functional return (Fig. 46-2). Reinnervation is always a slow process.

Successfully realigned nerves remyelinate, grow to their former size, and eventually have conduction velocities at most of their former capacity. Successful reinnervation is slowed by infection and increasing age. Disorganization of the nerve or mismatched realignments may result in functional weakness, unintentional muscle movements, and poor sensation.

Some sensory function may return before the regeneration process can occur. This is because nerves above the injured neurons are stimulated to produce collateral innervation to the affected areas. These collaterals occur before the axon has regenerated sufficiently.

FIG. 46-2 Regeneration of peripheral nerve after injury.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient may relate a history of extremity or pelvic trauma, penetrating injury, recent surgery, or the use of crutches. Peripheral nerve trauma is especially common in wartime combat. In addition to weakness or flaccid *paralysis*, the patient may report *burning sensations* below the trauma or pain that increases with touch or environmental stimulation. Observe for skin and nail changes of the affected extremities.

Perform a physical assessment to determine which neurologic functions are intact. In acute trauma, the injury should first be evaluated by the physician to determine whether movement is contraindicated. If movement is not contraindicated, the patient's motor function is assessed by putting the limb through the normal range of motion. Any abnormal movements, tremor, atrophy, contractions, paresis or paralysis, and weak or absent deep tendon reflexes are documented. Ask the patient about abnormal sensations.

After complete denervation, the extent of vasomotor function is reflected in skin temperature, skin color, and edema. A warm phase and a cold phase have been identified. During the **warm phase**, the extremity is warm and the skin appears flushed or rosy. Over 2 to 3 weeks, this phase is gradually superseded by a **cold phase**, during which the skin appears cyanotic, mottled, or reddish blue and feels cool compared with the unaffected extremity. Use the dorsal surface of your hand to compare skin temperatures because the abundance of temperature receptors in this area provides more accurate assessments. Edema may be noted immediately after injury or later as a result of surgical procedures. Record any evidence of trophic changes (e.g., scaling of skin, brittleness of nails, loss of body hair). This initial assessment serves as the baseline for comparison during subsequent examinations, which are performed every 2 to 4 hours or less frequently as the patient's condition indicates.

INTERVENTIONS

Interventions for the patient with peripheral nerve trauma depend on the location as well as the type and degree of injury. If the nerve trauma results from a primary lesion, such as a tumor, the underlying problem is addressed first.

The health care provider may prescribe immobilization of the involved area by splint, cast, or traction to provide the rest needed to limit and resolve any inflammation. The purpose of surgical management is to restore the function of the damaged nerve. There are usually no special preoperative interventions for the patient undergoing peripheral nerve repair. Chapter 16 describes the general care of the patient before surgery.

If the nerve is lacerated or transected, surgery may be indicated. Restorative procedures include resecting and suturing to realign the severed nerve ends, nerve grafts, and nerve and tendon transplants.

The timing of procedures to repair nerves has been controversial. In the past, a repair delay of 3 to 8 weeks after injury allowed associated injuries to heal, after which the surgeon could better assess the extent of nerve damage. Although microsurgery and the use of lasers now allow primary nerve repair at the time of injury, the surgeon's judgment in selecting the optimal time and surgical procedure remains crucial.

After an injury, the two severed nerve segments contract and may form scar tissue. Before surgical anastomosis, the surgeon dissects these stumps to remove any damaged nerve tissue. This further decreases the lengths of the ends to be joined. To compensate for this shortening and to avoid excessive tension on the sutured nerve, the involved extremity is positioned in exaggerated flexion. The surgeon aligns the segments under magnification, bringing the nerve fiber ends together, and then sutures the nerve tissue.

After suturing, the extremity is placed in a cast to maintain the flexed position and to avoid tension on the suture line. Ten to 14 days after nerve repair, the entire dressing is removed, the joint flexion is eased, and a new splint may be applied for an additional 2 weeks. At that time, a removable splint may be applied and physical therapy begun. Protection of the nerve sutures is continued for a minimum of 6 weeks.

If a large segment of nerve has been damaged and direct anastomosis would be impossible without stretching the

nerve, the surgeon may insert a *nerve graft*. Motor and sensory axons may regenerate through the graft, joining the nerve segments through the two sites of anastomosis. The results of grafting are not usually as favorable as with direct anastomosis. Immobilization by splints or casts to facilitate healing of the surgical sites is essential.

Splints are usually held in place with elastic wrapping or hook-and-loop (Velcro) closures, which can become too tight if edema develops.

! NURSING SAFETY PRIORITY

Critical Rescue

Perform frequent neurovascular assessments after surgical nerve repair, including checking the skin around the splints and casts (hourly, initially) for tightness, warmth, and color. If the patient reports discomfort, tingling, or coolness or if the color is blanched, the cast or splint may be too tight (constricted). Inform the physician immediately about constriction and any indication of drainage under a splint or cast.

Skin care is essential. Atrophy of the epidermis and underlying tissue causes the skin to become more fragile and more susceptible to injury and breakdown. Decreased skin nutrition and vascularity associated with denervation cause delayed healing, which further worsens the problem. Thoroughly examine the skin for evidence of irritation or injury, and assist or instruct the patient to wash and dry the involved areas carefully. If the skin is dry, lanolin or cocoa butter may be used as a lubricant. *Because sensation may be absent or inhibited, teach the patient to protect the involved areas from temperature extremes and other sources of potential trauma.*

Physical or occupational therapy is the major approach for rehabilitation after surgical repair. Reinforce and help the patient perform the exercises learned in these therapy sessions. Because the regeneration of nerves and subsequent return of sensory and motor function may be extremely slow and produce pain, the patient may become discouraged and depressed. If the disability is permanent, he or she needs encouragement and assistance to cope with the changes in body image, self-esteem, and lifestyle.

RESTLESS LEGS SYNDROME

Pathophysiology

Restless legs syndrome (RLS) is characterized by leg paresthesias (burning, prickly sensation) associated with an irresistible urge to move. Over 10% of the population in the United States have the problem, and women are affected twice as often as men (National Institute of Neurological Disorders and Stroke, 2011a). The most common type is associated with peripheral and central nerve damage in the legs and spinal cord. Many of those affected with *primary RLS* have a positive family history, indicating a possible genetic basis. The incidence is higher in patients who have diabetes mellitus type 2 and chronic kidney disease. Other potential risk factors include:

- Polyneuropathies
- Advanced age
- Sleep deprivation

- Drugs such as antinausea drugs, antipsychotic drugs, and selective serotonin reuptake inhibitors
- Caffeine and alcohol

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient reports intense burning or “crawling-type” sensations in the legs and therefore feels the need to move them repeatedly. These symptoms are worse in the evening and at night and when the patient is still for a period of time. Patients feel they need to move to relieve the symptoms. Many move their legs periodically while sleeping. For that reason, they often refer to themselves as “night walkers.”

INTERVENTIONS

The management of RLS is symptomatic and involves treating the underlying cause or contributing factor, if known. Both nonpharmacologic measures and drug therapy are used. Teach patients to avoid as many risk factors as possible or make lifestyle modifications. Examples are avoiding caffeine and alcohol, quitting smoking, losing weight, and exercising.

Strategies to relieve the symptoms of RLS include walking, stretching, moderate exercise, or a warm bath. Teach the patient ways to decrease insomnia such as limiting caffeine, nicotine, and alcohol and setting a routine bedtime. Strenuous activity should not be done 2 to 3 hours before bedtime. Although few research studies support their use, massage, biofeedback, and acupuncture may be effective. Many patients benefit from support groups. Refer them to The Restless Legs Foundation (www.rls.org) as an excellent resource for information and patient and family support.

Many of the drugs prescribed for RLS are also used for either Parkinson disease (PD) or epilepsy. *Dopamine agonists* such as pramipexole (Mirapex) and ropinirole (Requip) are oral drugs used extensively. Gabapentin enacarbil (Solzira) is an *antiepileptic drug (AED)* that was recently approved by the FDA for RLS. These agents are usually taken at bedtime.

Some patients have had success with *Sinemet*, a combination of levodopa and carbidopa. This drug is often given with other medications to be more effective in reducing the symptoms of the disease. The usual dosage is between 50 and 200 mg at bedtime each day.

Other classes of drugs for managing RLS include *benzodiazepines*, such as *diazepam (Valium)*, and *opioids* as a last resort. Two other AEDs, carbamazepine (Tegretol) and gabapentin (Neurontin), have been particularly effective and are taken in divided doses throughout the day.

For insomnia from RLS, the herbs *melatonin* and *valerian* may be effective for many people, especially older adults (National Institute of Neurological Disorders and Stroke, 2011a). Teach patients to inform their health care providers when adding these supplements.

DISEASES OF THE CRANIAL NERVES

Patients with cranial nerve disease may be seen in any practice settings. The cranial nerves may be affected in association with other disorders of the nervous system or as a result of

FIG. 46-3 Distribution of the trigeminal nerve and its three divisions: ophthalmic, maxillary, and mandibular.

trauma. The most common disorders, those affecting cranial nerves V (trigeminal) and VII (facial), are discussed here.

TRIGEMINAL NEURALGIA

Pathophysiology

Trigeminal neuralgia (TN) is also known as *tic douloureux*. According to the [National Institute of Neurological Disorders and Stroke \(2011b\)](#), trigeminal neuralgia:

- Is a disease that affects the trigeminal, or fifth cranial, nerve.
- Occurs more often in people older than 50 years and in women more often than men.
- Causes a specific type of facial pain, which occurs in sudden, intense facial spasms.
- Is usually provoked by minimal stimulation of a trigger zone (like dental procedures).
- Is unilateral (one-sided) and confined to the area innervated by the trigeminal nerve, most often the second and third branches ([Fig. 46-3](#)).
- Is familial due to an inherited pattern of blood vessel formation. Patients younger than 30 years with pain in more than one branch of the trigeminal nerve may be further evaluated to rule out the possibility of a tumor or multiple sclerosis.

The cause of trigeminal neuralgia is thought to be related to impaired inhibitory mechanisms in the brainstem caused by excessive firing of irritated fibers in the trigeminal nerve. In addition, trauma and infection of the teeth, jaw, or ear may be contributing factors.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

TN is a chronic pain syndrome. It can be categorized into two types of pain: classic and atypical. When describing classic pain, patients use terms such as “excruciating,” “sharp,”

“shooting,” “piercing,” “burning,” and “jabbing.” Between bursts of pain, which last from seconds to minutes, there is usually no pain. Often no sensory or motor deficits are found on examination, but the condition can be agonizing for the patient. The fear of precipitating attacks often causes patients to avoid talking, smiling, eating, or attending to hygienic needs such as shaving, washing the face, and brushing the teeth. The pain can cause uncontrollable facial twitching.

The course of trigeminal neuralgia (TN) involves bouts of classic pain for several weeks or months followed by spontaneous remissions. The length of these remissions may vary from days to years, but attack-free periods tend to become shorter as the patient grows older. Symptoms rarely disappear permanently.

By contrast, patients describe atypical pain as a continuous burning sensation that involves the entire face. He or she may not have any remission periods. Some patients experience both types of pain ([Alexander, 2007](#)).

The patient suspected of TN usually has a computed tomography (CT) scan and MRI. The diagnosis is made based on patient history and the results of these tests.

INTERVENTIONS

The priority for care of the patient with TN is pain management. Specific interventions are determined by the amount of pain he or she is experiencing. Drug therapy is the first choice, but surgery may be needed for some patients.

Drug Therapy and Radiosurgery

The first choice for drug therapy is carbamazepine (CBZ, Tegretol), an antiepileptic drug (AED), discussed in [Chapter 44](#). Other drugs, such as gabapentin (Neurontin), which is another AED, pregabalin (Lyrica), and muscle relaxants such as baclofen (Lioresal, Kemstro), may be used. Some patients also achieve pain relief with complementary therapies, such as acupuncture ([Lui et al., 2010](#)).

When medical management fails or to supplement medical management, radiosurgery techniques such as a peripheral chemical nerve block with ropivacaine or stereotactic radiation treatments with the Gamma Knife® may be used. These procedures prevent the complications of major surgery, such as a craniotomy, but may need to be repeated for recurrent pain. [Lemos et al. \(2010\)](#) found that patients who had a nerve block with ropivacaine and took carbamazepine had the best pain control when compared with those patients with either treatment alone.

In some cases, a **percutaneous stereotactic rhizotomy (PSR)** is performed as an ambulatory care procedure under general anesthesia. The surgeon passes a hollow needle through the inside of the patient’s cheek into the trigeminal nerve fibers. A heating current (radiofrequency thermocoagulation) goes through the needle to destroy some of the fibers. The entire nerve is not destroyed. The advantages of this procedure include long-term pain relief, tolerance by older adults, absence of facial paralysis, and preservation of the sensation of touch. Puncturing the internal carotid artery is a possible complication. The affected side is permanently insensitive to pain.

After the PSR procedure, apply an ice pack to the PSR operative site on the cheek and jaw for 3 to 4 hours. Perform a focused cranial nerve assessment to assess whether other nerves have been damaged (e.g., facial nerve). Discourage the

patient from chewing on the affected side until paresthesias resolve. A soft diet is usually prescribed.

NURSING SAFETY PRIORITY

Action Alert

Teach the patient who has had percutaneous stereotactic rhizotomy to avoid rubbing the eye on the affected side because the protective mechanism of pain will no longer warn of injury. Instruct him or her to inspect the eye daily for redness or irritation and report to the physician any change or blurred vision. Stress the importance of regular dental examinations because the absence of pain may not warn the patient of potential problems.

As an option to heat, a balloon microcompression may be performed. The balloon compresses the trigeminal nerve root. A glycerol injection may also be used as an option, but it is not done as commonly as thermocoagulation.

Surgical Management

Surgery is performed if the patient cannot tolerate the side effects of drug therapy or if radiosurgical techniques are not feasible. A common surgical procedure is a craniotomy with microvascular decompression (MVD), which must be performed by a neurosurgeon.

In addition to the general preoperative care provided to all patients, the surgeon thoroughly explains the surgical benefits and any expected neurologic deficits. Ensure that the patient understands the procedure to be performed and any risks or complications.

In some patients, a small artery compresses the trigeminal nerve as it enters the pons. Surgical relocation of this artery (**microvascular decompression**) may relieve the pain of TN without compromising facial sensation. This procedure is more invasive, requiring a craniotomy. Though not common, complications include aseptic meningitis, cerebrospinal fluid leak, ataxia, **ipsilateral** (same side) hearing loss, and facial nerve damage. Older adults and patients with other medical problems may not be candidates for this procedure.

In addition to general post-craniotomy care for patients as described in **Chapter 47**, monitor the patient who has microvascular decompression for signs of complications including headache, cranial nerve dysfunction, and bleeding. Assess his or her corneal reflex, extraocular muscles, and facial nerve, and report abnormal findings to the surgeon. Document all changes promptly.

DECISION-MAKING CHALLENGE

Patient-Centered Care; Safety

An older patient visits the medical clinic with reports of shooting, electric-like pain on the right side of her face. She reports that the pain gets worse when she brushes her teeth or washes her face. After a complete neurologic examination, the neurologist diagnoses her as having trigeminal neuralgia. She is placed on carbamazepine (Tegretol).

1. What is the priority for this patient's care?
2. What health teaching will you provide for this patient about her disease?
3. What will you teach her about the medication that has been prescribed?
4. What options for treatment will she have if the drug is not effective in relieving her pain?
5. What other care will you include in your health teaching?

Psychosocial considerations for the patient with trigeminal neuralgia include disappointment with ineffective drug protocols or surgical procedures, as well as the fear that the pain may recur with any activity. The patient may fail to move the face in an attempt to prevent pain. This behavior may be misinterpreted by others as withdrawal or depression. Refer patients and their families to the TNA—Facial Pain Association (www.fpa-support.org) for more information and support. TNA of Canada (www.catna.ca) is the national organization in Canada that advocates and informs patients and their families about trigeminal neuralgia.

FACIAL PARALYSIS

Pathophysiology

Facial paralysis, or **Bell's palsy**, is an acute paralysis of cranial nerve VII but may also affect cranial nerves V (trigeminal) and VIII (vestibulocochlear [auditory]). The condition is also known as *cranial polyneuritis*. Although the incidence may be slightly higher among people with diabetes, Bell's palsy occurs in all ages; however, it is more commonly seen in young adults.

Acute maximum paralysis is attained within 48 hours in about half the patients and within 5 days in almost all of them. Pain behind the ear or on the face may occur before paralysis by a few hours or days. The disorder involves a drawing sensation and paralysis of all facial muscles on the affected side. The patient cannot close his or her eye, wrinkle the forehead, smile, whistle, or grimace. He or she may also lose the ability for the eye to tear or may have excessive tearing. The face appears masklike and sags. Taste is usually impaired to some degree, but this symptom seldom persists beyond the second week of paralysis. Tinnitus (ringing in the ears) may also occur. Most patients go into remission within 3 months.

The cause of Bell's palsy is believed to be the result of an inflammatory process triggered by a formerly dormant herpes simplex virus type 1 (HSV-1). Infections or exposure to cold may trigger the HSV-1 to cause symptoms of the disease. Patients are rarely hospitalized, but the nurse may encounter them in community-based settings such as clinics, physicians' offices, or emergency departments.

PATIENT-CENTERED COLLABORATIVE CARE

Medical management usually includes corticosteroids, 30 to 60 mg daily, during the first week after the onset of symptoms. Antiviral drugs such as acyclovir (Zovirax), famciclovir (Famvir), or valacyclovir (Valtrex) may be prescribed for 7 to 10 days after symptoms begin. Mild analgesics may help relieve the pain. Nursing care is directed toward managing the major neurologic deficits and providing psychosocial support. Because the eye does not close, the cornea must be protected from drying and subsequent ulceration or abrasion. Teach the patient to manually close the eyelid at intervals and to instill artificial tears during the day. An ointment to supply moisture can be used at night. The eye may be patched or taped closed at bedtime.

The patient may be unable to chew, sip fluids through a straw, or control drooling on the affected side. Thus mealtime may become a problem. Encourage the patient to eat and

drink using the unaffected side of the mouth. Frequent, small meals may be better tolerated, and patients may require a soft diet. Explain how to use simple techniques of massage; the application of warm, moist heat; and facial exercises. In some cases, physical therapy is prescribed for these treatments. As muscle tone improves, teach the patient to grimace, wrinkle the brow, force the eyes closed, whistle, and blow air out of the cheeks three or four times daily for 5 minutes in front of a mirror.

Nerve blocks or surgery may be performed, but these procedures are not common. Surgery is reserved for patients with complete, severe Bell's palsy to decompress the facial nerve. In some cases, cosmetic surgery is done.

Although most patients recover fully within a few weeks or months, some may experience residual weakness. A few have permanent neurologic deficits. For chronic pain, gabapentin (Neurontin) may be prescribed. These patients require a great deal of support because body image and self-esteem are drastically affected. Provide both information and psychosocial support. Refer patients and their families to the Bell's Palsy Research Foundation for information (www.angelfire/az/BellsPalsy.com). The Bell's Palsy Association in the United Kingdom is also a good source of web-based information (www.bellsalsy.org.uk).

NURSING CONCEPT REVIEW

What might you NOTICE if a patient is experiencing impaired mobility and/or sensation as a result of acute or chronic peripheral nervous system disorders?

- Report of loss of sensation in extremities or face
- Report of muscle weakness
- Inability to ambulate
- Inability to move legs and/or arms
- Difficulty breathing
- Report of burning, tingling sensations in extremities
- Report of pain in extremities or face
- Ptosis

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired mobility and/or sensation as a result of peripheral nervous system disorders?

Perform and interpret physical assessment, including:

- Performing a complete neurologic assessment
- Assessing a patient's airway and breathing ability (if difficulty breathing is noticed)
- Performing a comprehensive pain assessment

Respond by:

- Notifying health care provider or contacting Rapid Response Team if patient has problems with breathing or experiences a sudden change in neurologic status
- Establishing an airway and promoting ease in breathing (e.g., putting patient in sitting position, providing oxygen)
- Having emergency equipment like ventilator and tracheostomy set available for patient who has respiratory compromise
- Assisting with ambulation and ADLs as needed
- Providing analgesics and other pain relief measures

On what should you REFLECT?

- Continue to observe patient for changes in muscle weakness, paralysis, and respiratory function.
- Monitor patient for decreased report of pain and associated symptoms.
- Think about ways to promote independence in mobility and self-care.
- Think about health care team members with whom you will need to collaborate to improve mobility.
- Develop a teaching plan for the patient and family for continuing care.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with members of the interdisciplinary team, including the health care provider, physical and occupational therapists, speech-language pathologist, and dietitian, for care of patients with Guillain-Barré syndrome (GBS) and myasthenia gravis (MG).
- Refer patients with peripheral nervous system (PNS) disorders to community support groups and health care organizations, such as The Restless Legs Syndrome Foundation and the Myasthenia Gravis Foundation.

Health Promotion and Maintenance

- Teach patients on cholinesterase inhibitor drugs and their families about clinical manifestations of cholinergic and myasthenic crises as listed in Table 46-3.
- Reinforce the need for patients with MG to take their drugs on time.

Psychosocial Integrity

- Provide alternatives to promote communication for patients with GBS and MG, including speaking slowly, lip-reading, and using communication boards or electronic technology.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd**Physiological Integrity**

- Assess for changes in respiratory status and muscle function for patients with GBS and MG.
- Recall that patients with GBS have ascending paralysis, sensory changes, cranial nerve involvement, and autonomic manifestations as a result of demyelination of neurons (see [Chart 46-1](#)).
- Note that patients with MG have an autoimmune disease in which muscle weakness, including ocular symptoms, is the result of attacks on the acetylcholine receptors at neuromuscular junctions (see [Chart 46-3](#)).
- Prevent and manage common complications of plasmapheresis as described in [Chart 46-2](#).
- Teach patients which factors can worsen or exacerbate MG as listed in [Table 46-4](#).
- Remember that the priority for care for patients with GBS and MG is respiratory monitoring and airway management.
- Assess patients with GBS and MG for the risk for complications of immobility, such as pressure ulcers; take measures to prevent these problems.
- For patients having a thymectomy, maintain adequate respiratory function and observe for complications such as pneumothorax or hemothorax (e.g., chest pain, shortness of breath).
- Perform frequent neurovascular assessments for patients having a peripheral nerve repair.
- Teach patients with restless legs syndrome to minimize risk factors for the disorder, including exercising, losing weight, and quitting smoking.
- Recall that trigeminal neuralgia (TN) affects primarily the fifth cranial nerve (although others may be involved). Facial paralysis (Bell's palsy) affects cranial nerve VII.
- The priority for care of the patient with TN is pain management.
- After surgery for TN, perform a focused cranial nerve assessment to determine damage to the nerves, such as CN VII.

CHAPTER

47

Care of Critically Ill Patients with Neurologic Problems

Rachel L. Palmieri and Donna D. Ignatavicius

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges

Audio Glossary

Concept Map Creator

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the importance of collaborating with health care team members when planning and providing care for critically ill patients with neurologic problems.
2. Prioritize care for patients with a stroke or traumatic brain injury (TBI).
3. Identify community resources for patients with severe neurologic problems and their families.
4. Discuss the importance of maintaining continuous care between the hospital and community-based agencies for patients discharged with a stroke, head injury, or brain tumor.

Health Promotion and Maintenance

5. Develop a teaching plan about risk factors for having a stroke.
6. Describe how to perform a comprehensive neurologic assessment of patients who have a stroke.

Psychosocial Integrity

7. Identify the need to assess the family's response to a brain cancer diagnosis and treatment options.
8. Discuss how to support the patient and family coping with life changes that often result from a TBI or stroke.
9. Assess the needs of patients with stroke who have altered sensory perception.

Physiological Integrity

10. Differentiate clinical manifestations and management of patients with a transient ischemic attack (TIA) and stroke.
11. Perform a focused neurologic assessment of patients who are critically ill.
12. Assess the patient on fibrinolytic therapy for potential adverse effects.
13. Develop and evaluate an evidence-based plan of care for the patient with a stroke.
14. Assess patients for adverse responses to TBI, such as increased intracranial pressure (ICP).
15. Develop a plan of care for interventions to prevent increasing ICP.
16. Manage care for the patient experiencing increased ICP.
17. Develop a postoperative plan of care for the patient having a craniotomy.
18. Prevent and monitor for postoperative complications of a craniotomy.
19. Explain the role of chemotherapy, radiation, and surgery in the management of patients with brain tumors.
20. Explain the primary focus for management of patients with a brain abscess.

Some neurologic problems can cause patients to become critically ill or die. Stroke, head injury, brain tumor, and brain abscess are examples that can lead to life-threatening increased intracranial pressure (ICP). Permanent neurologic dysfunction or death may be prevented by early recognition and aggressive management of this complication by the bedside staff nurse. Serious and severe neurologic problems cause varying degrees of impaired *mobility, sensation, and cognition*. These impairments may be temporary or permanent and mild or severe depending on the nature of the health problem.

TRANSIENT ISCHEMIC ATTACK AND REVERSIBLE ISCHEMIC NEUROLOGIC DEFICIT

Ischemic strokes often follow warning signs such as a **transient ischemic attack (TIA)** (also called a *silent stroke*) or a **reversible ischemic neurologic deficit (RIND)** (Chart 47-1). Both warning signs cause temporary neurologic dysfunction resulting from a *brief* interruption in cerebral blood flow, possibly due to cerebral vasospasm or systemic arterial hypertension. The difference between a TIA and a RIND is the length of time the patient is symptomatic. A TIA lasts a few minutes to fewer than 24 hours, whereas RIND symptoms last longer than 24 hours but less than a week. Typically, symptoms of a TIA resolve within 30 to 60 minutes. It is not unusual for symptoms to resolve by the time the patient reaches the emergency department (ED). Both TIAs and RINDs may damage the brain tissue with repeated insults, as seen on magnetic resonance imaging (MRI) or computed tomography (CT). Multiple TIAs indicate a high stroke risk.

Upon admission to the ED, the patient is stabilized as necessary. A complete neurologic assessment is performed, and routine laboratory work, electrocardiogram, and CT scan are done. Patients older than 65 years and those with diabetes, symptoms lasting longer than 10 minutes, or motor or speech difficulties often are admitted. At discharge, the patient is usually placed on anticoagulant therapy (e.g., clopidogrel [Plavix]) unless medically contraindicated. As part of the discharge processes, ensure that the patient is aware of bleeding precautions and the actions to take should bleeding occur. Anticoagulant therapy is discussed in detail in [Chapter 38](#) in the Venous Thromboembolism section. Reinforce the need to

follow up with the health care provider and to complete any diagnostic tests requested on an ambulatory care basis.

STROKE (BRAIN ATTACK)

Pathophysiology

A **stroke** is caused by a change in the normal blood supply to the brain. The National Stroke Association uses the term **brain attack** to better describe a stroke. Both terms are used in clinical practice. *Any stroke is a medical emergency that strikes suddenly, and it should be treated immediately to prevent neurologic deficit and permanent disability.*

Stroke is the third leading cause of death in the United States and is considered a major disability worldwide. According to the Centers for Disease Control and Prevention, approximately 136,000 Americans die each year from stroke (Centers for Disease Control and Prevention [CDC], 2011).

Pathophysiologic Changes in the Brain

The brain cannot store oxygen or glucose and therefore must receive a constant flow of blood to provide these substances for normal function. In addition, blood flow is important for the removal of metabolic waste (e.g., carbon dioxide, lactic acid). If blood supply to any part of the brain is interrupted for more than a few minutes, cerebral tissue dies (**infarction**). The result is varying degrees of disability, depending on the location and amount of brain tissue affected. Brain metabolism and blood flow after a stroke are affected around the infarction as well as in the **contralateral** (opposite side) hemisphere. Effects of a stroke on the contralateral (nonaffected) side may be due to brain swelling and further changes in blood flow throughout the brain. As a result of brain swelling, patients may develop clinical manifestations of increasing intracranial pressure, a potentially life-threatening complication.

Types of Strokes

Strokes are generally classified as ischemic (occlusive) or hemorrhagic ([Fig. 47-1](#)). Acute ischemic strokes are either thrombotic or embolic in origin ([Table 47-1](#)). Most strokes are ischemic.

Ischemic Stroke. An acute **ischemic stroke** (AIS) is caused by the occlusion (blockage) of a cerebral artery by either a thrombus or an embolus. A stroke that is caused by a **thrombus** (clot) is referred to as a **thrombotic stroke**, whereas a stroke caused by an **embolus** (dislodged clot) is referred to as an **embolic stroke**.

Thrombotic Stroke. Thrombotic strokes account for more than half of all strokes and are commonly associated

CHART 47-1 KEY FEATURES

Transient Ischemic Attack

Visual Deficits

- Blurred vision
- Diplopia (double vision)
- Blindness in one eye
- Tunnel vision

Motor Deficits

- Weakness (arm, hand, or leg)
- Gait disturbance (ataxic)

Sensory Deficits

- Numbness (face, arm, or hand)
- Vertigo

Speech Deficits

- Aphasia
- Dysarthria (slurred speech)

FIG. 47-1 Types of stroke/brain attack.

with the development of atherosclerosis in either intracranial or extracranial arteries (usually the carotid arteries). Atherosclerosis is the process by which fatty plaques develop on the inner wall of the affected arterial vessel. [Chapter 38](#) describes this health problem, including its pathophysiology, in more detail.

Rupture of one or more plaques exposes foam cells to clot-promoting elements in the blood. The end result is clot formation. If the clot is of sufficient size, it may interrupt blood flow to the brain tissue supplied by the vessel, causing an occlusive stroke. This process may occur over many years because collateral circulation to the involved area develops to compensate for the occlusion. The [bifurcation](#) (point of division) of the common carotid artery and the vertebral arteries at their junction with the basilar artery are the most common sites involved. Because of the gradual occlusion (blockage) of the arteries, thrombotic strokes tend to have a *slow* onset, evolving over minutes to hours.

Embolic Stroke. An embolic stroke is caused by a thrombus or a group of thrombi that break off from one area of the body and travel to the cerebral arteries via the carotid artery or vertebrobasilar system. The usual source of emboli is the heart. Emboli can occur in patients with nonvalvular atria fibrillation, ischemic heart disease, rheumatic heart disease, mural thrombi after a myocardial infarction (MI), or insertion of a prosthetic heart valve. Another source of emboli may be plaque that breaks off from the carotid sinus or internal carotid artery. Emboli tend to become lodged in the smaller cerebral blood vessels at their point of bifurcation or where the lumen narrows.

The middle cerebral artery (MCA) is most commonly involved in an embolic stroke. As the emboli occlude the vessel, ischemia develops and the patient experiences the clinical manifestations of the stroke. However, the occlusion may be temporary if the embolus breaks into smaller fragments, enters smaller blood vessels, and is absorbed. For these reasons, embolic strokes are characterized by the *sudden*

development and rapid occurrence of neurologic deficits. The symptoms may resolve over several hours or a few days. Conversion of an occlusive stroke to a hemorrhagic stroke may occur because the arterial vessel wall is also vulnerable to ischemic damage from blood supply interruption. Sudden hemodynamic stress may result in vessel rupture, causing bleeding directly within the brain tissue.

Hemorrhagic Stroke. The second major classification of stroke is hemorrhagic stroke. In this type of stroke, vessel integrity is interrupted and bleeding occurs into the brain tissue or into the space surrounding the brain (usually intracerebral or subarachnoid).

Intracerebral hemorrhage (ICH) describes bleeding into the brain tissue generally resulting from severe hypertension. Elevated blood pressure (BP) leads to changes within the arterial wall that leave it likely to rupture. Damage to the brain occurs from bleeding, causing edema, distortion, and displacement, which are direct irritants to brain tissue. Hemorrhagic strokes occur more often with sudden, dramatic blood pressure elevations, such as those seen with cocaine abuse.

Subarachnoid hemorrhage (SAH) is much more common and results from bleeding into the subarachnoid space, the space between the pia mater and arachnoid layers of the meninges covering the brain. This type of bleeding is usually caused by a ruptured aneurysm or arteriovenous malformation ([Mink & Miller, 2011b](#)).

An [aneurysm](#) is an abnormal ballooning or blister along a normal artery, which usually develops in a weak spot on the artery wall, typically along the posterior circulation such as the basilar artery, vertebral artery, or the superior cerebral artery. Larger aneurysms are more likely to rupture than smaller ones.

Aneurysm rupture causes bleeding into the subarachnoid space, the ventricles, and/or intracerebral tissue. [Vasospasm](#), a sudden and periodic constriction of a cerebral artery, often results from a cerebral hemorrhage due to an aneurysm

TABLE 47-1 DIFFERENTIAL FEATURES OF THE TYPES OF STROKE

FEATURE	ISCHEMIC		HEMORRHAGIC
	THROMBOTIC	EMBOLIC	
Evolution	Intermittent or stepwise improvement between episodes of worsening Completed stroke	Abrupt development of completed stroke Steady progression	Usually abrupt onset
Onset	Gradual (minutes to hours)	Sudden	Sudden, may be gradual if caused by hypertension
Level of consciousness	Preserved (patient is awake)	Preserved (patient is awake)	Deepening stupor or coma
Contributing associated factors	Hypertension Atherosclerosis	Cardiac disease	Hypertension Vessel disorders
Prodromal symptoms	Transient ischemic attack		
Neurologic deficits	Deficits during the first few weeks Slight headache Speech deficits Visual problems Confusion	Maximum deficit at onset Paralysis Expressive aphasia	Focal deficits Severe, frequent
Cerebrospinal fluid	Normal; possible presence of protein	Normal	Bloody
Seizures	No	No	Usually
Duration	Improvements over weeks to months Permanent deficits possible	Rapid improvements	Variable Permanent neurologic deficits possible

FIG. 47-2 Appearance of an arteriovenous malformation. Note the dilated, entangled blood vessels.

rupture. Blood flow to distal areas of the brain supplied by the artery is markedly diminished, which leads to cerebral ischemia and infarction and further neurologic dysfunction.

An **arteriovenous malformation (AVM)** is an uncommon abnormality that occurs during embryonic development. It is a tangled or spaghetti-like mass of malformed, thin-walled, dilated vessels (Fig. 47-2). The congenital absence of a capillary network forms an abnormal communication between the arterial and venous systems. The vessels may eventually rupture, causing bleeding into the subarachnoid space or into the intracerebral tissue, because normally the capillary network lowers the pressure between the arterial and venous systems. In the absence of the capillary network, the thin-walled veins are subjected to arterial pressure.

Etiology and Genetic Risk

Like that of many health problems, the causes of stroke are likely a combination of genetic and environmental risk factors. Major risk factors increase the likelihood of strokes and can be divided into those that can be modified and those that cannot (nonmodifiable factors). Many of these factors have a familial or genetic predisposition and are discussed elsewhere in this text. For example, first-order relative (mother, father, sister, brother) stroke risk increases with a strong family history of hypertension or atherosclerotic disease. Relatives of a patient with an aneurysm may be at higher risk for intracranial aneurysms and should consider diagnostic testing and follow-up.

Incidence/Prevalence

It is estimated that there are more than 4.7 million stroke survivors in the United States. About 730,000 strokes occur each year, but deaths have declined over the past 15 years. The number of strokes occurring in the younger adult population is increasing as a result of chronic IV drug abuse. Those using crack cocaine experience an increased incidence of stroke resulting from changes in the clotting mechanism caused by the drugs, spasm of cerebral vessels, or hemodynamic stress from the sudden increase in systolic blood pressure.

Some patients who have had strokes have another one within 1 year. Strokes tend to occur more often in the southern United States (“stroke belt”), which may be related to the larger older population, tobacco use, and obesity.

Although stroke symptoms can appear at any time of the day or night, researchers have found that there is a circadian

CHART 47-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Common Modifiable Risk Factors for Developing a Stroke

- Smoking
- Substance abuse (particularly cocaine)
- Obesity
- Sedentary lifestyle
- Oral contraceptive use
- Heavy alcohol use
- Use of phenylpropanolamine (PPA), found in antihistamine drugs

pattern with a peak incidence between 6 AM and noon and the lowest incidence between midnight and 6 AM (Beal, 2010).

Health Promotion and Maintenance

In 2007, the American Heart Association/American Stroke Association completed an exhaustive review of risk factors that contribute to stroke. These risk factors have been divided into three groups: risk factors that cannot be changed, risk factors that can be changed with medical treatment, and risk factors that can be changed by lifestyle modification.

People with predisposing health conditions should be aware that they could have a stroke unless they change their lifestyle habits (Chart 47-2). Teach them the importance of seeking professional health care and adhering to the recommended treatment plan. Also remind them that other risk factors contribute to health problems such as a sedentary lifestyle and high-fat diet. Recommend a diet high in fruits and vegetables and low in saturated and *trans* fats. Light to moderate alcohol consumption may reduce the risk for stroke, but a higher consumption may increase it. Additional information about lifestyle modifications, such as weight control and smoking cessation, can be found elsewhere in this text. Table 47-2 lists common risk factors that *cannot* be changed (nonmodifiable) and those that may be altered with appropriate care management.

CULTURAL AWARENESS

American Indian/Alaskan Native groups have the highest prevalence of stroke. Black men and women have more strokes than white men and women. Hispanic or Latino men have more strokes than non-Hispanic men (Summers et al., 2009). Mexican Americans with atrial fibrillation have more recurrent strokes than non-Hispanic whites (see the Evidence-Based Practice box on p. 1008). The causes for these differences are not well known, but genetic, environmental, and/or lifestyle factors may play a role, including dietary habits.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement by a client about preventing stroke indicates a need for further teaching by the nurse?

- A. “I am going to join Alcoholics Anonymous to help me stop drinking.”
- B. “I only smoke cigars, which is better than smoking cigarettes.”
- C. “I need to walk at least 5 days a week to increase my exercise level.”
- D. “I need to lose at least 30 pounds to get my BMI into normal range.”

TABLE 47-2 RISK FACTORS FOR DEVELOPING STROKE THAT CANNOT BE CHANGED OR CAN BE ALTERED WITH COLLABORATIVE MANAGEMENT

Risk factors that cannot be changed:

1. Age: Risk for stroke increases as a person gets older.
2. Sex: Men have a 30% higher incidence of stroke, but postmenopausal women are also at a significantly higher risk.
3. Family history: If a person has a stroke, it increases the risk for stroke in other family members.
4. Race: African Americans have a higher risk for stroke because of their increased incidence of high blood pressure, obesity, and diabetes.
5. Myocardial infarction (MI): A history of an MI puts the patient at increased risk for a stroke.
6. History of migraine headaches: Patients who suffer from migraines may be at higher risk for ischemic strokes.
7. A prior stroke: Patients who have strokes are at risk for another stroke.
8. Sickle cell disease: Patients with this type of disorder are at risk for stroke at a younger age.
9. Berry aneurysms: These are small sac-like areas in the wall of an artery in the brain and commonly are found at junctions of vessels at the base of the brain; they can rupture without warning, causing bleeding within the brain.

Risk factors that can be altered with collaborative management:

1. High blood pressure (HBP): HBP can be managed with a combination of drug therapy, diet, and exercise.
2. High cholesterol levels: Patients with high cholesterol can reduce their stroke risk by 30% through lifestyle changes and drug therapy.
3. Transient ischemic attacks (TIAs): When patients have symptoms of TIA, they must seek medical attention immediately for anticoagulation therapy to prevent the possibility of a stroke.
4. Cardiovascular disease: Atherosclerosis and atrial fibrillation are major risk factors for stroke, but if diagnosed early, they can be controlled with drug therapy.
5. Diabetes: Consistent diabetic control is essential to decrease the risk for strokes.
6. Blood clotting disorders: Patients with clotting problems are at high risk for thrombotic stroke and require preventive anticoagulants.
7. Sleep apnea: Patients with sleep apnea have 3 to 6 times the risk for stroke. Weight loss and/or using a breathing device at night called a *continuous positive airway pressure (CPAP)* machine can manage this problem.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

An accurate history is important in the diagnosis of a stroke. The information obtained assists in identifying the area of the brain involved, as well as the cause.

If possible, obtain a history of the patient's activity when the stroke began. Ischemic strokes often occur during sleep, whereas hemorrhagic strokes tend to occur during activity. Next ask the patient or a family member how the symptoms progressed. Be sure to document the history of the stroke's onset. Symptoms of an embolic or hemorrhagic stroke tend to occur abruptly, whereas thrombotic strokes generally have a more gradual progression. Determine the severity of

EVIDENCE-BASED PRACTICE

Are Some Ethnic Groups More Likely to Have Recurrent Strokes Than Others?

Simpson, J.R., Zahuranec, D.B., Lisabeth, L.D., Sanchez, B.N., Skolarus, L.E., Mendizabal, J.E., et al. (2010). Mexican Americans with atrial fibrillation have more recurrent strokes than do non-Hispanic whites. *Stroke*, 41(10), 2132-2136.

Atrial fibrillation is a common risk factor for acute ischemic stroke. The researchers used surveillance methods from the Brain Attack Surveillance in Corpus Christi Project to determine recurrence rates in patients who had both atrial fibrillation and a history of at least one stroke. A total of 236 patients were studied over an 8-year period.

Mexican Americans (MAs) are the largest group of Hispanic Americans and have a higher incidence of stroke than non-Hispanic whites (NHWs). However, little is known about the post-stroke differences in these groups. This study demonstrated that the recurrence and severity of stroke was significantly higher in the MA population who had atrial fibrillation when compared with the NHW group.

Level of Evidence: 4

The study is descriptive but used a large sample over a prolonged period of time in one geographic area.

Commentary: Implications for Practice and Research

Nurses need to be aware of which ethnic groups are most at risk for strokes, especially those with atrial fibrillation. Although the study was limited to one geographic area, the number of subjects illustrates the need for health teaching. Atrial fibrillation is a treatable and controllable risk factor. Teach patients about the importance of adherence to the treatment regimen. Aggressive stroke prevention is essential.

the symptoms, such as whether they worsened after the initial onset (hemorrhagic stroke) or began to improve (embolic stroke). It is important to determine whether the symptoms come and go, possibly indicating a transient ischemic attack (TIA) or a reversible ischemic neurologic deficit (RIND).

During the interview, observe the patient's level of consciousness (LOC) and assess for indications of intellectual or memory impairments or difficulties with speech or hearing. Question the patient or family member about the presence of any sensory or motor changes, visual problems, problems with balance or gait, and changes in reading or writing abilities.

In addition, ask about the patient's medical history with specific attention directed toward a history of head trauma, diabetes, hypertension, heart disease, anemia, and obesity. Obtain a list of current medications, including prescribed drugs, over-the-counter (OTC) drugs, herbal and nutritional supplements, and recreational (illicit) drugs. To complete the history, obtain data about the patient's social history, including education, employment, travel, leisure activities, and personal habits (e.g., smoking, diet, exercise pattern, drug and alcohol use).

The patient with a cerebral aneurysm often reports the onset of a sudden, severe headache described as "the worst headache of my life." Additional symptoms include nausea and vomiting, photophobia, cranial neuropathy, stiff neck, and change in mental status. There may also be a family history of aneurysms.

Physical Assessment/Clinical Manifestations

First responder personnel (e.g., paramedics, emergency medical technicians) perform an initial neurologic examination using well-established stroke assessment tools.

! NURSING SAFETY PRIORITY

Critical Rescue

In the ED, evaluate the stroke patient within 10 minutes of arrival. This same standard applies to patients already hospitalized for other medical conditions who have a stroke. The priority is assessment of ABCs—**a**irway, **b**reathing, and **c**irculation. Many hospitals have designated stroke teams and centers that are expert in acute stroke management.

ED nurses perform a complete neurologic assessment on admission. The National Institutes of Health Stroke Scale (NIHSS) is a commonly used valid and reliable assessment tool that nurses complete as soon as possible after the patient arrives in the ED (Table 47-3). The NIHSS includes 11 areas of assessment and serves as the patient's baseline (Mink & Miller, 2011a). The most important area to assess is the patient's level of consciousness (LOC). Use the Glasgow Coma Scale (see Fig. 43-10 in Chapter 43 on p. 918) to frequently monitor for changes in LOC that could indicate increased intracranial pressure. Specific patient manifestations depend on the extent and location of the ischemia and the arteries involved (Chart 47-3).

Cognitive Changes. The patient may have a variety of cognitive problems in addition to changes in LOC. LOC varies depending on the extent of increased intracranial pressure (ICP) caused by the stroke and on the location of the stroke. Assess for:

- Denial of the illness
- Spatial and **proprioceptive** (awareness of body position in space) dysfunction
- Impairment of memory, judgment, or problem-solving and decision-making abilities
- Decreased ability to concentrate and attend to tasks

Dysfunction in one or more of these areas may be severe depending on the hemisphere involved (Chart 47-4).

The *right* cerebral hemisphere is more involved with visual and spatial awareness and **proprioception** (sense of body position). A person who has a stroke involving the right cerebral hemisphere is often unaware of any deficits and may be disoriented to time and place. Personality changes include impulsivity (poor impulse control) and poor judgment. The *left* cerebral hemisphere, the dominant hemisphere in all but about 15% to 20% of the population, is the center for language, mathematic skills, and analytic thinking. Therefore a left hemisphere stroke results in **aphasia** (inability to use or comprehend language), **alexia** or **dyslexia** (reading problems), **agraphia** (difficulty with writing), and **acalculia** (difficulty with mathematic calculation). A complete assessment of these problems is performed by a speech-language pathologist (SLP).

Motor Changes. The motor examination provides information about which part of the brain is involved. A **right hemiplegia** (paralysis on one side of the body) or **hemiparesis** (weakness on one side of the body) indicates a stroke involving the *left* cerebral hemisphere because the motor nerve fibers cross in the medulla before entering the spinal

CHART 47-3 KEY FEATURES

Stroke Syndromes

Middle Cerebral Artery Strokes

- Contralateral hemiparesis: arm > leg
- Contralateral sensory deficit
- Homonymous hemianopsia
- Unilateral neglect or inattention
- Aphasia, anomia, alexia, agraphia, and acalculia
- Impaired vertical sensation
- Spatial deficit
- Perceptual deficit
- Visual field deficit
- Altered level of consciousness: drowsy to comatose

Posterior Cerebral Artery Strokes

- Perseveration (word or action repetition)
- Aphasia, amnesia, alexia, agraphia, visual agnosia, and ataxia
- Loss of deep sensation
- Decreased touch sensation
- Stupor; coma

Internal Carotid Artery Strokes

- Contralateral hemiparesis
- Sensory deficit
- Hemianopsia, blurred vision, blindness
- Aphasia (dominant side)
- Headache
- Bruit

Anterior Cerebral Artery Strokes

- Contralateral hemiparesis: leg > arm
- Bladder incontinence
- Personality and behavior changes
- Aphasia and amnesia
- Positive grasp and sucking reflex
- Perseveration
- Sensory deficit (lower extremity)
- Memory impairment
- Apraxic gait

Vertebrobasilar Artery Strokes

- Headache and vertigo
- Coma
- Memory loss and confusion
- Flaccid paralysis
- Areflexia, ataxia, and vertigo
- Cranial nerve dysfunction
- Disconjugate gaze
- Visual deficits (uniorbital) and homonymous hemianopsia
- Sensory loss: numbness

cord and periphery. On the other hand, a *left* hemiplegia or hemiparesis indicates a stroke in the *right* cerebral hemisphere. If the brainstem or cerebellum is affected, the patient may experience hemiparesis or quadriparesis and **ataxia** (gait disturbance).

In collaboration with the physical therapist (PT) and occupational therapist (OT), assess the patient's muscle tone. The patient with **hypotonia**, or **flaccid paralysis**, cannot overcome the forces of gravity, and the extremities tend to fall to the side. The extremities feel heavy, and muscle tone is inadequate for balance, equilibrium, or protective mechanisms. **Hypertonia** (**spastic paralysis**) tends to cause fixed positions or contractures of the involved extremities. Range of motion (ROM) of the joints is restricted, and shoulder

TABLE 47-3 NIH STROKE SCALE

CATEGORY AND MEASUREMENT	SCORE*
1a. Level of Consciousness (LOC) 0 = Alert; keenly responsive. 1 = Not alert; but arousable by minor stimulation to obey, answer, or respond. 2 = Not alert; requires repeated stimulation to attend or is obtunded and requires strong or painful stimulation to make movements (not stereotyped). 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, and areflexic.	_____
1b. LOC Questions 0 = Answers two questions correctly. 1 = Answers one question correctly. 2 = Answers neither question correctly.	_____
1c. LOC Commands 0 = Performs two tasks correctly. 1 = Performs one task correctly. 2 = Performs neither task correctly.	_____
2. Best Gaze 0 = Normal. 1 = Partial gaze palsy; gaze is abnormal in one or both eyes, but forced deviation or total gaze paresis is not present. 2 = Forced deviation, or total gaze paresis not overcome by the oculocephalic maneuver.	_____
3. Visual 0 = No visual loss. 1 = Partial hemianopia. 2 = Complete hemianopia. 3 = Bilateral hemianopia (blind including cortical blindness).	_____
4. Facial Palsy 0 = Normal symmetrical movements. 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling). 2 = Partial paralysis (total or near-total paralysis of lower face). 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face).	_____
5. Motor (Arm) 0 = No drift; limb holds 90 (or 45) degrees for full 10 seconds. 1 = Drift; limb holds 90 (or 45) degrees, but drifts down before full 10 seconds; does not hit bed or other support. 2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity. 3 = No effort against gravity; limb falls. 4 = No movement. Untestable = Amputation or joint fusion.	Right arm: _____ Left arm: _____
6. Motor (Leg) 0 = No drift; leg holds 30-degree position for full 5 seconds. 1 = Drift; leg falls by the end of the 5-second period but does not hit bed. 2 = Some effort against gravity; leg falls to bed by 5 seconds, but has some effort against gravity. 3 = No effort against gravity; leg falls to bed immediately. 4 = No movement. Untestable = Amputation or joint fusion.	Right leg: _____ Left leg: _____
7. Limb Ataxia 0 = Absent. 1 = Present in one limb. 2 = Present in two limbs. Untestable = Amputation or joint fusion	_____
8. Sensory 0 = Normal; no sensory loss. 1 = Mild-to-moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched. 2 = Severe-to-total sensory loss; patient is not aware of being touched in the face, arm, and leg.	_____

Continued

TABLE 47-3 NIH STROKE SCALE—cont'd

CATEGORY AND MEASUREMENT	SCORE*
9. Best Language 0 = No aphasia; normal. 1 = Mild-to-moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation on ideas expressed or form of expression. 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by the listener. 3 = Mute, global aphasia; no usable speech or auditory comprehension.	_____
10. Dysarthria 0 = Normal. 1 = Mild-to-moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty. 2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to any dysphasia, or is mute/anarthric. Untestable = Intubated or other physical barrier.	_____
11. Extinction and Inattention (Neglect) 0 = No abnormality. 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities. 2 = Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space.	_____

*The patient can have a score of 0 to 40, with 0 having no neurologic deficits and 40 being the most deficits.

Modified from National Institutes of Health Stroke Scale, 2003. www.ninds.nih.gov/doctors/NIH_stroke_scale.pdf.

CHART 47-4 KEY FEATURES

Left and Right Hemisphere Strokes

FEATURE	LEFT HEMISPHERE*	RIGHT HEMISPHERE
Language	Aphasia Agraphia Alexia	Impaired sense of humor
Memory	Possible deficit	Disorientation to time, place, and person Inability to recognize faces
Vision	Inability to discriminate words and letters Reading problems Deficits in the right visual field	Visual spatial deficits Neglect of the left visual field Loss of depth perception
Behavior	Slowness Cautiousness Anxiety when attempting a new task Depression or a catastrophic response to illness Sense of guilt Feeling of worthlessness Worries over future Quick anger and frustration Intellectual impairment	Impulsiveness Lack of awareness of neurologic deficits Confabulation Euphoria Constant smiling Denial of illness Poor judgment Overestimation of abilities (risk for injury)
Hearing	No deficit	Loss of ability to hear tonal variations

*Location for speech in all but 15% to 20% of people.

subluxation may easily occur from either spasticity or flaccidity. Also assess proprioception, head and trunk control, balance, coordination, and gait. The patient who has had a stroke may also be unable to use an object correctly (**agnosia**) or carry out a purposeful motor activity or speech (**apraxia**).

Loss of neurologic control by the cerebral cortex causes a spastic (upper motor neuron) uninhibited bladder. Bowel

function may also be affected. Assess the patient for incontinence (most common) or retention of urine and stool. Some patients have both problems.

Sensory Changes. The sensory examination evaluates the patient's response to touch and painful stimuli. In addition to diminished motor function, decreased sensation typically occurs on the affected side of the body.

Evaluate for indications of **unilateral body neglect syndrome**, which is particularly common with strokes in the **right cerebral hemisphere**. In this syndrome, the patient is unaware of the existence of his or her left or paralyzed side. The typical picture is that of the patient sitting in a wheelchair and leaning to the left with the arm caught in the wheelchair wheel. When questioned, the patient often states that everything is fine and believes that he or she is sitting up straight in the chair. The patient may wash or dress only one side of the body.

Another important part of the nursing assessment focuses on visual ability. Infarction or ischemia involving the carotid artery may cause pupil constriction or dilation, **ptosis** (eyelid drooping), visual field deficits, or pallor and petechiae of the conjunctiva. **Amaurosis fugax**, a brief episode of blindness in one eye, results from retinal ischemia caused by ophthalmic or carotid artery insufficiency. **Hemianopsia**, or blindness in half of the visual field, results from damage to the optic tract or occipital lobe. Usually this deficit occurs as **homonymous hemianopsia**, in which there is blindness in the same side of both eyes (Fig. 47-3). The patient with this condition must turn his or her head to scan the complete range of vision. Otherwise, he or she does not see half of the visual field. For example, the patient eats only half of a meal because that is the only portion seen. Patients with brainstem or cerebellar damage may have abnormal eye movements, such as nystagmus (involuntary movements of the eyes).

Cranial Nerve Function. Assess the patient's ability to chew, which reflects the function of cranial nerve (CN) V. Assessment of the patient's ability to swallow reflects the

FIG. 47-3 A, Site of lesions causing visual loss. 1, Total blindness left eye; 2, Bitemporal hemianopia; 3, Left homonymous hemianopia. **B,** Visual fields corresponding to lesions shown in **A**. 1, Total blindness left eye; 2, Bitemporal hemianopia; 3, Left homonymous hemianopia.

function of CNs IX and X. In addition, note any facial paralysis or paresis (CN VII), absent gag reflex (CN IX), or impaired tongue movement (CN XII). The patient who has difficulty chewing or swallowing foods and liquids (**dysphagia**) is at risk for aspiration pneumonia and may become constipated or dehydrated from inadequate fluid intake.

Cardiovascular Assessment. Patients with embolic strokes may have a heart murmur, dysrhythmias (most often atrial fibrillation), or hypertension. It is not unusual for the patient to be admitted to the hospital with a blood pressure greater than 180 to 200/110 to 120 mm Hg. Although a somewhat higher blood pressure (150/100 mm Hg) is needed to maintain cerebral perfusion after an acute ischemic stroke, pressures above this limit may lead to another stroke.

Psychosocial Assessment

The typical patient with a stroke is older than 60 years, is hypertensive, and has varying degrees of motor weakness and level of consciousness. Language and cognitive deficits, as well as behavior and memory problems, may also occur.

Assess the patient's reaction to the illness, especially in relation to changes in body image, self-concept, and ability to perform ADLs. In collaboration with the patient's family and friends, identify any problems with coping or personality changes.

Ask about the patient's financial status and occupation, because they may be affected by the residual neurologic deficits of the stroke. Patients who do not have disability or health insurance may worry about how their family will cope financially with the disruption in their lives. Early involvement of social services, certified hospital chaplain, or psychological counseling may enhance coping skills.

Assess for **emotional lability**, especially if the frontal lobe of the brain has been affected. In such cases, the patient laughs and then cries unexpectedly for no apparent reason. Explain these uncontrollable emotions to the family or significant others so they do not feel responsible for these reactions.

Laboratory Assessment

Clinical history and presentation are usually enough to identify a stroke once it has occurred. No definitive laboratory tests confirm its diagnosis. Elevated hematocrit and hemoglobin levels are often associated with a severe or major stroke as the body attempts to compensate for lack of oxygen to the brain. An elevated white blood cell (WBC) count may indicate the presence of an infection, possibly subacute bacterial endocarditis, or a response to physiologic stress or inflammation. The health care provider typically requests a prothrombin time (PT) or international normalized ratio (INR) and a partial thromboplastin time (PTT) to establish baseline information in case anticoagulation therapy is started. These diagnostic tests may also provide supportive evidence that a hemorrhagic stroke has occurred.

Imaging Assessment

Brain imaging is the most important tool for confirming the diagnosis of a stroke. *Computed tomography (CT)* without contrast is the standard for initial diagnosis (Mink & Miller, 2011b). Cerebral aneurysms, if large enough, may also be identified. For a patient with an ischemic or occlusive stroke, the head CT is usually initially negative, indicating thrombotic or embolic stroke rather than intracerebral hemorrhage. After the first 24 hours, CT shows progressive changes of ischemia, infarction, and associated cerebral edema. This test is invaluable in establishing baseline information for future comparison in case the patient's condition deteriorates. In addition, the scan enables the physician to identify pathologic changes that may mimic a stroke, such as a brain tumor or cerebral hematoma, both of which may be unrelated to cerebrovascular disease.

Magnetic resonance imaging demonstrates ischemic brain injury earlier than CT. Magnetic resonance angiography and multimodal techniques such as perfusion-weighted imaging enhance the sensitivity of the MRI to detect early changes in the brain, including confirming blood flow. Ultrasonography

(carotid duplex scanning) and echocardiography help determine additional cardiovascular risks.

Other Diagnostic Assessment

To assist in the determination of a cardiac cause of a stroke, the health care provider may request a 12-lead electrocardiogram (ECG) and an evaluation of cardiac enzymes. As with other cardiovascular diseases, it is not unusual to find these changes on the ECG: inverted T wave, ST depression, and prolongation of the QT interval in the cardiac cycle.

ANALYSIS

The priority problems for patients with a stroke are:

1. Inadequate perfusion to the brain related to interruption of arterial blood flow and a possible increase in ICP
2. Impaired Swallowing related to neuromuscular impairment
3. Impaired Physical Mobility and Self-Care Deficit related to neuromuscular impairment or cognitive impairment
4. Aphasia or dysarthria related to decreased circulation in the brain or facial muscle weakness
5. Urinary and/or Bowel Incontinence related to reflex bladder and bowel
6. Sensory changes related to altered neurologic reception, transmission, and perception
7. Unilateral body neglect syndrome related to disturbed perceptual abilities or hemianopsia

PLANNING AND IMPLEMENTATION

Improving Cerebral Perfusion

Planning: Expected Outcomes. The patient with a stroke is expected to have an adequate blood flow to the brain and through the cerebral blood vessels to maintain brain function and prevent further brain injury.

Interventions. Interventions for patients experiencing strokes are determined primarily by the type and extent of the stroke. For patients having ischemic strokes, the standard of practice is to start two IV lines with non-dextrose isotonic saline (Summers et al., 2009). The immediate primary role of the nurse is to manage the patient receiving treatment and continuously assess for increasing intracranial pressure.

Nonsurgical Management. Nursing interventions are initially aimed at monitoring for neurologic changes or complications associated with stroke and its treatment. The two major treatment modalities for patients with acute ischemic stroke are fibrinolytic therapy and endovascular interventions. If the thrombus is lodged in one of the carotid arteries, an endarterectomy may be performed. Regardless of the immediate management approach used, once the patient is stable, provide ongoing supportive care. Provide interventions to prevent and/or monitor for early signs of complications, such as hyperglycemia, urinary tract infection, and pneumonia. Implement interventions to prevent patient falls. These health problems are discussed in appropriate chapters in this textbook.

Fibrinolytic Therapy. For select patients with ischemic strokes, early intervention with fibrinolytic therapy (“clot-busting drug”) is the standard of practice to improve blood flow to or through the brain. The success of fibrinolytic therapy from a stroke depends on the interval between the

time the patient was last seen normal (LSN) and available treatment. It also depends on where the treatment is given. Hospitals with stroke centers or specialized stroke teams who care for numerous stroke patients have lower mortality rates than those hospitals that care for fewer of these patients (Bederson et al., 2009).

Intravenous (systemic) fibrinolytic therapy (also called *thrombolytic therapy*) for an acute ischemic stroke (AIS) dissolves the cerebral artery occlusion to re-establish blood flow and prevent cerebral infarction. Recombinant tissue plasminogen activator (rtPA [Retavase]) is the only drug approved at this point for the treatment of acute ischemic stroke. Thrombolytics activate plasminogen, which degrades the thrombus by breaking down fibrin. The most important factor in whether or not to give rtPA is the time LSN. The standard window for eligibility is 3 hours from time LSN. However, in 2009, the American Stroke Association recommended an expanded time interval from 3 to 4.5 hours for patients unless they fall into the following categories:

- Age older than 80
- Anticoagulation with an international normalized ratio less than or equal to 1.7
- Baseline National Institutes of Health Stroke Scale greater than 25
- History of both stroke and diabetes

WOMEN'S HEALTH CONSIDERATIONS

Women typically have 30% lower odds of receiving tissue plasminogen activator (tPA) than men. These disparities are very concerning because tPA is the only approved therapy to reduce the functional limitations caused by ischemic stroke and there is evidence that women have better outcomes from tPA than men. The reasons for lower tPA rates in women are not yet fully understood. Advocate for women by teaching them about this finding, and discuss the importance of coming to the ED in a timely fashion as soon as stroke symptoms begin (Beal, 2010).

Fibrinolytic therapy is explained to the patient and/or family member, and informed consent is obtained. The dosage of the drug is based on the patient's actual weight. Each hospital has strict protocols for mixing and administering rtPA and for monitoring the patient before and after rtPA administration.

! NURSING SAFETY PRIORITY

Drug Alert

In addition to frequent monitoring of vital signs, carefully observe for signs of intracerebral hemorrhage and other signs of bleeding during administration of rtPA. Other best practice interventions are listed in Chart 47-5.

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client receiving IV sodium heparin after a dose of rtPA (Retavase) begins to have severe epistaxis. What is the nurse's first action?

- A. Slow the heparin infusion to keep the vein open.
- B. Call the health care provider immediately.
- C. Check the INR and prothrombin time levels.
- D. Stop the infusion immediately.

CHART 47-5 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nursing Interventions During and After IV Administration of rtPA

- Infuse 0.9 mg/kg (maximum dose 90 mg) over 60 minutes with 10% of the dose given as a bolus over 1 minute.
- Admit the patient to a critical care or specialized stroke unit.
- Perform neurologic assessments, including vital signs, every 10 to 15 minutes during infusion and every 30 minutes after that for at least 6 hours; monitor hourly for 24 hours after treatment.
- If systolic blood pressure is 180 mm Hg or greater or diastolic is 105 mm Hg or greater, give antihypertensive drugs as prescribed.
- Do not place invasive tubes, such as NG tubes or indwelling urinary catheters, until patient is stable to prevent bleeding.
- Discontinue the infusion if the patient reports severe headache or has severe hypertension, bleeding, nausea, and/or vomiting; notify the health care provider immediately.
- Obtain a follow-up CT scan after treatment before starting antiplatelet or anticoagulant drugs.

rtPA, Recombinant tissue plasminogen activator.

Endovascular Interventions. Endovascular procedures include intra-arterial thrombolysis using drug therapy and mechanical **embolectomy** (clot removal). Intra-arterial thrombolysis has the advantage of delivering the fibrinolytic agent directly into the thrombus within 6 hours of the stroke's onset. It is particularly beneficial for some patients who have an occlusion of the middle cerebral artery or those who arrive in the ED after the window for rtPA. If the patient arrives in less than 8 hours, the interventional neuroradiologist may perform mechanical embolectomy using special instrumentation systems that can remove the clot by suction or other method (Mink & Miller, 2011a). Patients having either fibrinolytic therapy or endovascular interventions are admitted to the critical care setting for intensive collaborative monitoring.

Some patients may have worsening of their neurologic status starting within 24 to 48 hours after their stroke. A major complication is increased intracranial pressure (ICP) (Chart 47-6). Reassess patients every 1 to 4 hours (depending on severity of the condition) using the approved assessment tools.

Monitoring for Increased Intracranial Pressure. The patient is most at risk for increased ICP resulting from edema during the first 24 to 48 hours after onset of the stroke.

! NURSING SAFETY PRIORITY

Critical Rescue

Be alert for symptoms of increased ICP in the stroke patient, and report any deterioration in the patient's neurologic status to the health care provider immediately! The first sign of increased ICP is a declining level of consciousness (LOC).

Keep the head of the bed (HOB) elevated to between 25 and 30 degrees to prevent a decreased blood flow to the brain. The best HOB positioning has not yet been determined, and more studies are needed to determine best practice. Provide oxygen therapy to prevent hypoxia for patients with oxygen saturation less than 92% or those with a decreased LOC

CHART 47-6 KEY FEATURES

Increased Intracranial Pressure (ICP)

- Decreased level of consciousness (LOC) (lethargy to coma)
- Behavior changes: restlessness, irritability, and confusion
- Headache
- Nausea and vomiting (may be projectile)
- Change in speech pattern
- Aphasia
- Slurred speech
- Change in sensorimotor status
- Pupillary changes: dilated and nonreactive pupils ("blown pupils") or constricted and nonreactive pupils
- Cranial nerve dysfunction
- Ataxia
- Seizures (usually within first 24 hrs after stroke)
- Cushing's triad
- Severe hypertension
- Widened pulse pressure
- Bradycardia
- Abnormal posturing:
 - Decerebrate (extensor)
 - Decorticate (flexion)

(Summers et al., 2009). Maintain the head in a midline, neutral position to help promote venous drainage from the brain. When severe hemiparesis is present, position the patient on his or her side to prevent aspiration and promote comfort.

In collaboration with other team members, avoid patient care activities that may increase ICP, especially if the patient has indications of cerebral edema. Avoid positioning the patient in extreme hip and neck flexion. Extreme hip flexion may increase intrathoracic pressure, which may make ICP more difficult to control. Extreme neck flexion interferes with venous drainage from the brain, also affecting ICP control.

Additional nursing considerations include avoiding the clustering of nursing procedures (e.g., giving a bath followed immediately by changing the bed linen) within a short time. This action is needed because the effect on ICP elevation is more dramatic when multiple activities are clustered within a narrow time period. Hyperoxygenating the patient before suctioning may also be appropriate to avoid even transient hypoxemia and resultant ICP elevation from dilation of cerebral arteries. Assess the necessity of suctioning because it increases ICP.

A quiet environment is particularly important for the patient experiencing a headache, which is common with an aneurysm or increased ICP. The patient may have **photophobia** (sensitivity to light). Therefore keep the room lights very low.

Monitor vital signs closely, at least every 1 to 2 hours. Notify the health care provider if the blood pressure exceeds acceptable levels. Generally, the health care provider allows the patient with *acute ischemic stroke* to be slightly hypertensive (a systolic blood pressure [SBP] between 140 and 150 mm Hg) to promote cerebral tissue perfusion. A higher blood pressure (above 180 mm Hg systolic and/or 110 mm Hg diastolic) could lead to a hemorrhagic stroke or rebleeding of an aneurysm (if present).

Evidence-based guidelines are not available for managing blood pressure in patients with hemorrhagic strokes, but for

many patients, severe hypertension is the cause of their stroke (Mink & Miller, 2011b).

! NURSING SAFETY PRIORITY

Critical Rescue

If the stroke patient's SBP is more than 200 mm Hg, notify the health care provider immediately to prescribe a continuous IV antihypertensive medication. Monitor the patient's BP and mean arterial pressure (MAP) every 5 minutes until the SBP is between 140 and 150 mm Hg to maintain brain perfusion. An ICP monitoring system may be used to ensure that cerebral perfusion pressure (CPP) is maintained.

Carefully monitor the patient's temperature because fever may cause increased ICP. Hypothermia may cause decreased cerebral perfusion. A complete discussion of the *management of increased ICP, including drug therapy, is on p. 1027 under Interventions in the Traumatic Brain Injury section.*

Patients admitted to a critical care unit are connected to a cardiac monitor and observed for dysrhythmias. The nurse performs a cardiac assessment, with particular attention directed toward auscultation of heart sounds to identify the presence of cardiac murmurs or atrial fibrillation (AF). Murmurs or AF may place the patient at increased risk for emboli. Close physical assessment for indications of hemodynamic stability is indicated. Invasive hemodynamic monitoring is often needed to monitor and evaluate physiologic stability and response to therapy.

Monitoring for Other Complications. Monitor the patient with an aneurysm or arteriovenous malformation (AVM) for signs and symptoms of hydrocephalus and vasospasm. **Hydrocephalus** (increased cerebrospinal fluid [CSF] within the ventricular and subarachnoid spaces) may occur as a result of blood in the CSF. This prevents CSF from being reabsorbed properly by the arachnoid villi. Cerebral edema, which interferes with the flow of CSF out from the ventricular system, may also develop. Eventually the ventricles become enlarged. If hydrocephalus is left untreated, increased intracranial pressure (ICP) results. Observe for clinical manifestations of hydrocephalus, which are similar to those of ICP elevation, including a change in the LOC. Clinical findings may also include headache, pupil changes, seizures, poor coordination, gait disturbances (if ambulatory), and behavior changes.

Clinical manifestations of vasospasm may include decreased LOC, motor and reflex changes, and increased neurologic deficits (e.g., cranial nerve dysfunction, motor weakness, and aphasia). The symptoms may fluctuate with the occurrence and degree of vasospasm present.

Rebleeding or rupture is a common complication for the patient with an aneurysm or AVM. It may occur within 24 hours of the initial bleed or rupture and up to 7 to 10 days later. Assess for severe headache, nausea and vomiting, a decreased LOC, and additional neurologic deficits. Potential consequences of aneurysm rebleeding may be catastrophic.

Ongoing Drug Therapy. Ongoing drug therapy depends on the type of stroke and the resulting neurologic dysfunction. In general, the purposes of drug therapy are to prevent further thrombotic episodes (anticoagulation) and to protect the neurons from hypoxia.

Although previously widely used, anticoagulants are controversial and are not considered current best practice by the

American Stroke Association for acute ischemic strokes or for preventing future strokes (Adams et al., 2007). Sodium heparin and other anticoagulants, such as warfarin (Coumadin, Warfilone), are **high-alert drugs** that can cause bleeding, including intracerebral hemorrhage.

However, an *initial* dose of 325 mg of enteric-coated or other form of aspirin (Ecotrin, Ancasal) is recommended within 24 to 48 hours after stroke onset. Aspirin should not be given within 24 hours of rtPA administration. These drugs are antiplatelet drugs and prevent blood clotting by reducing platelet adhesiveness (clumping). They can cause bruising, hemorrhage, and liver disease over a long-term period. Teach the patient to report any unusual bruising or bleeding to the health care provider. The 2007 best practice guidelines for the treatment of acute ischemic stroke recommend *against* the use of clopidogrel (Plavix) alone or in combination with aspirin (Adams et al., 2007). However, many health care providers still prescribe them.

To treat seizures, lorazepam (Ativan), a benzodiazepine, may be administered with close neurologic and cardiopulmonary monitoring. For long-term antiseizure therapy, the health care provider may also prescribe antiepileptic drugs (AEDs), such as phenytoin (Dilantin), gabapentin (Neurontin), or topiramate (Topamax). Neuroprotective drugs such as calcium channel blockers (e.g., nimodipine [Nimotop]) may be given to treat or prevent cerebral vasospasm after a subarachnoid hemorrhage. Vasospasm, which usually occurs between 4 and 14 days after the stroke, slows blood flow to the area and worsens ischemia. Calcium channel blockers work by relaxing the smooth muscles of the vessel wall and reducing the incidence and severity of the spasm. Neurologic functioning may improve, and further deterioration from ischemia is then prevented. In addition, these drugs dilate collateral vessels to ischemic areas of the brain. Although these neuroprotective and vasodilating drugs are sometimes used, the American Stroke Association does not recommend them (Adams et al., 2007). Stool softeners, analgesics for pain, and antianxiety drugs may also be prescribed as needed for symptom management. Stool softeners also prevent the Valsalva maneuver during defecation to prevent increased ICP.

Other Nonsurgical Interventions. With the refinement of vascular stents, carotid artery angioplasty with stenting (CAS) is common to *prevent* or, in some cases, help manage an acute ischemic stroke. This interventional radiology procedure is usually done under moderate sedation. It may be performed by a cardiovascular surgeon or interventional radiologist.

A technique using a **distal/embolic protection device** has made this procedure very safe. The device is placed beyond the stenosis through a catheter inserted into the femoral artery (groin). The device catches any clot debris that breaks off during the CAS procedure. Placement of a carotid stent is performed to open a blockage in the carotid artery typically at the division of the common carotid artery into the internal and external carotid arteries. Throughout the procedure, the patient's neurologic and cardiovascular status are assessed. CAS is less invasive, causes less blood loss, requires shorter hospital stays (overnight) and recovery time, and has fewer complications than a carotid endarterectomy. Postprocedure care is the same as that provided for a carotid endarterectomy (see Surgical Management on p. 1016).

A rare postprocedure complication, hyperperfusion syndrome, has a very high morbidity and mortality rate. This

syndrome is thought to be the result of an impaired auto-regulation of cerebral blood flow, which results from long-standing decreased cerebral perfusion pressure that occurs with carotid artery disease. The signs and symptoms include severe temporal headache, hypertension, seizures, and focal neurologic deficits. This syndrome may be associated with intracranial hemorrhage and may occur within 1 hour postprocedure up to 24 hours or even 1 week later (Oran & Oran, 2010).

The usual treatment of an *arteriovenous malformation (AVM)* uses interventional therapy to block abnormal arteries or veins and prevent bleeding from the vascular lesion. The same procedure may be performed to occlude the vessels surrounding an aneurysm. Under fluoroscopic guidance, the physician inserts a microcatheter into the carotid artery, typically using a femoral artery approach, and threads it to the vessel to be embolized. The physician then injects an embolic liquid agent to embolize the involved arteries (Fig. 47-4). When the liquid makes contact with the blood, it immediately hardens. Embolization is usually done before gamma knife or conventional surgery. (See later discussions of these procedures in this chapter.)

For clipping small aneurysms, a minimally invasive procedure using an endoscope (lighted tube) may be used. Other procedures that do not require a cranial incision are classified as *interventional radiology*. For example, an interventional neuroradiologist can direct a small catheter into the femoral artery and advance the catheter into the aneurysm. Specially designed, detachable platinum wire coils are placed into the aneurysm, which helps seal the area with a clot. It is predicted that this method will soon treat most intracranial aneurysms, thus avoiding craniotomies and their complications.

FIG. 47-4 Embolization procedure to treat an arteriovenous malformation. The liquid embolic agent travels to the area to cause vessel thrombosis.

Surgical Management. Few patients are candidates for surgery to treat strokes. The surgical procedure depends on the cause of the stroke.

Because of the frequent use of angioplasty and stenting, open carotid endarterectomy is becoming less common. This procedure may prevent progressing stroke in symptomatic patients with recurrent TIAs or carotid stenosis but usually is performed as an intervention to prevent strokes. The purpose of a **carotid endarterectomy** is to remove atherosclerotic plaque from the inner lining of the carotid artery. The procedure opens the artery enough to re-establish blood flow and decrease stroke risk.

The patient usually stays in the hospital for 2 nights unless complications occur or the patient is older. Postprocedure care involves monitoring vital signs, neurologic status, and peripheral pulses. Check the incision site for bleeding. Complications are not common, although stroke is possible. Monitor the patient for cerebral hyperperfusion, which may occur because of increased vascular pressure (from the open artery) and lead to intracranial hemorrhage (stroke).

! NURSING SAFETY PRIORITY

Action Alert

Before discharge after carotid endarterectomy, teach the patient to report these symptoms to the health care provider as soon as possible:

- Severe headache
- Change in brain function (e.g., drowsiness, decreased cognition)
- Muscle weakness
- Severe neck pain
- Neck swelling
- Hoarseness or difficulty swallowing (due to nerve damage)

In an **extracranial-intracranial bypass**, the surgeon performs a craniotomy (surgical opening into the brain through the skull) and bypasses the blocked artery by making a graft or a bypass from the first artery to the second artery. This procedure establishes blood flow around the blocked artery and re-establishes blood flow to the involved areas. The two most common techniques are the superficial temporal artery-to-middle cerebral artery (STA-MCA) graft and the occipital-to-posterior inferior cerebellar artery (PICA) bypass. Studies show that immediate surgery is associated with a high risk for intracranial hemorrhage and no improvement in outcome except in the patient with an embolus to the middle cerebral artery (Adams et al., 2007).

Whenever possible, an AVM is also totally removed via a craniotomy. The surgeon cuts and separates the group of vessels and removes the defect. Gamma radiation delivered through the gamma knife (see discussion on p. 1033 in the Stereotactic Radiosurgery section) produces fibrous thickening of the endothelial lining of the vessels to prevent further vessel enlargement and ultimately eliminate the lesion from the cerebral circulation. Improved microsurgical techniques have significantly reduced morbidity and mortality rates, and these procedures are becoming the treatment of choice in many medical centers.

Although not commonly done after a stroke, cerebral aneurysms may be repaired via a craniotomy as soon as the patient's condition is stabilized. Surgery may be postponed for patients

with ruptured aneurysms that caused stupor or coma, because their condition makes them high-risk surgical candidates. During surgery, the aneurysm is clipped or a clamp is placed at the base, or neck, of the aneurysm to prevent blood from entering the area. Visitors may be limited, and measures to decrease the patient's stress and increase comfort are usually initiated. The care of the patient having a craniotomy is discussed on p. 1033.

Managing Impaired Swallowing

Planning: Expected Outcomes. The patient with a stroke is expected to avoid aspiration and have adequate nutrition to promote health and prevent complications, including major weight loss.

Interventions. Aspiration is a frequent complication for patients with dysphagia (difficulty swallowing). Many of these aspirations are “silent” and are not recognized until pulmonary complications occur. The best practice for all stroke patients is to have them maintain an NPO status until their swallowing ability is assessed and a plan of care is developed for impaired swallowing. Before the patient is given any liquids, food, and medication, he or she must be screened for the ability to swallow. Follow agency guidelines for the screening procedure using an evidence-based bedside swallowing screening tool.

Observe for facial drooping, drooling, impaired voluntary cough, hoarseness, incomplete mouth closure, or cranial nerve palsies. Next check the gag and cough reflexes. If the patient does not pass this swallowing screen, collaborate with the speech-language pathologist (SLP) to conduct a bedside swallowing screening and evaluation. He or she may recommend a modified barium swallow (video fluoroscopy) to identify specific structures that are impaired during swallowing. *Ensure that the patient remains completely NPO status until the SLP determines that the patient can tolerate liquids or foods without aspirating.* Based on the complete swallowing evaluation, the SLP makes recommendations for feeding for the staff to follow. Remind all unlicensed assistive personnel (UAP) and the family about the need to follow these precautions exactly as they are written.

Some patients can swallow without difficulty but are at risk for aspiration because they are easily distracted and impulsive. These patients require a distraction-free environment with minimal disruption from television, visitors, or environmental noise. Observe for indications of fatigue, because it can significantly interfere with the patient's desire and ability to eat.

Studies indicate that as many as 50% of patients were malnourished at 2 to 3 weeks after a severe stroke (Summers et al., 2009). To avoid this complication, collaborate with the dietitian as needed to provide an accurate, comprehensive nutritional assessment on admission and throughout the hospital stay. Implement nutritional interventions, such as an early gastrostomy or oral nutrition, by at least the 3rd or 4th hospital day to prevent weight loss, an altered immune status, increased length of stay, and increased mortality (Summers et al., 2009).

For patients who can tolerate oral foods and liquids, follow the SLP's recommendations for thickened liquids, head positioning, and patient teaching to prevent aspiration. Teach UAP and family members how to follow these instructions, and have them readily available for reference.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client with a confirmed acute ischemic stroke is admitted to the medical unit after evaluation in the emergency department. What is the nurse's priority action on admission?

- A. Ask the nursing technician to weigh the client and record it.
- B. Consult with the physical therapist about the client's rehabilitative care.
- C. Keep the client NPO until the swallowing assessment is complete.
- D. Give warfarin and check activated thromboplastin levels.

Improving Mobility and Promoting Self-Care

Planning: Expected Outcomes. The patient with a stroke is expected to ambulate and provide self-care independently, with or without an assistive-adaptive device.

Interventions. Patients who have had a stroke often have flaccid or spastic paralysis. It is not unusual for the patient to eventually have a flaccid arm and spastic leg on the affected side because the affected leg often regains function more quickly than the arm. Patients begin rehabilitation as soon as possible to regain function and prevent complications of immobility, such as pneumonia, atelectasis, and pressure ulcers.

NURSING SAFETY PRIORITY

Action Alert

Be sure to support the affected flaccid arm of the stroke patient, and teach UAP to avoid pulling on it. Position the arm on a pillow while the patient is sitting to prevent it from hanging freely, which could cause shoulder subluxation. The physical or occupational therapist provides a sling-like device to support the arm during ambulation.

Another major complication of impaired physical mobility is the development of venous thromboembolism (VTE), especially deep vein thrombosis (DVT) that can lead to a pulmonary embolism (PE). This risk is highest in older patients and those with a severe stroke. Provide care to prevent this complication by applying sequential compression stockings or pneumatic compression boots, changing the patient's position frequently, and ambulating the patient if possible. Report any indications of DVT to the health care provider, and document assessments in the patient's chart. [Chapter 38](#) discusses VTE in detail.

The rehabilitation therapists evaluate the patient's ability to perform mobility skills, basic ADLs, and household tasks that will be performed at home. After a thorough evaluation, collaborate with them to develop a plan of care to promote patient independence, with or without assistive or adaptive devices. Therapy begins in the hospital setting and continues after discharge in most cases. [Chapter 8](#) describes interventions for improving mobility and promoting self-care.

Promoting Effective Communication

Planning: Expected Outcomes. The patient with a stroke is expected to receive, interpret, and express spoken, written, and nonverbal messages, if possible. However, some patients may need to develop strategies for alternative methods of communication, such as pictures or nonverbal language.

TABLE 47-4 TYPES OF APHASIA

Expressive

- Referred to as *Broca's*, or *motor*, *aphasia*
- Difficulty speaking
- Difficulty writing

Receptive

- Referred to as *Wernicke's*, or *sensory*, *aphasia*
- Difficulty understanding spoken words
- Difficulty understanding written words
- Speech often meaningless
- Made-up words

Mixed

- Combination of difficulty understanding words and speech
- Difficulty with reading and writing

Global

- Profound speech and language problems
- Often no speech or sounds that cannot be understood

Interventions. Language or speech problems are usually the result of a stroke involving the dominant hemisphere. The left cerebral hemisphere is the speech center in most patients. Speech and language problems may be the result of aphasia or dysarthria. Whereas aphasia is caused by cerebral hemisphere damage, **dysarthria** (slurred speech) is due to a loss of motor function to the tongue or to the muscles of speech, causing facial weakness and slurred speech. Involvement of the speech-language pathologist (SLP) as early as possible in the hospitalization greatly increases the patient's chances for optimal recovery. Remind patients to practice their exercises for dysarthria to strengthen their facial and oral muscles.

Aphasia can be classified in a number of ways. Most commonly, it is classified as expressive, receptive, or mixed (Table 47-4). **Expressive (Broca's, or motor) aphasia** is the result of damage in Broca's area of the frontal lobe. It is a motor speech problem in which the patient generally understands what is said but cannot communicate verbally. He or she also has difficulty writing but may be able to write. Rote speech and automatic speech such as responses to a greeting are often intact. The patient is aware of the deficit and may become frustrated and angry. Reassure patients and remind them to talk slowly.

Receptive (Wernicke's, or sensory) aphasia is due to injury involving Wernicke's area in the temporoparietal area. The patient cannot understand the spoken and often the written word. Although he or she may be able to talk, the language is often meaningless. Neologisms (made-up words) are common parts of speech.

Usually the patient has some degree of dysfunction in the areas of both expression and reception. This is known as *mixed aphasia*. Reading and writing ability are equally affected. Few patients have just expressive or receptive aphasia. In most cases, though, one type is dominant.

To help communicate with the patient with aphasia, use these guiding principles:

- Present one idea or thought in a sentence (e.g., "I am going to help you get into the chair").
- Use simple one-step commands rather than ask patients to do multiple tasks.

- Speak slowly but not loudly; use cues or gestures as needed.
- Avoid "yes" and "no" questions for patients with expressive aphasia, because they often give automatic responses that may be incorrect.
- Use alternative forms of communication if needed, such as a computer, communication board, or flash cards (often with pictures).

For more specific communication strategies for your patient, collaborate with the SLP.

Promoting Continence

Planning: Expected Outcomes. The patient with a stroke is expected to control elimination of urine and stool.

Interventions. The patient may be incontinent of urine and stool because of an altered level of consciousness, impaired innervation to the bladder and rectum, and/or the inability to communicate the need to urinate or defecate. Before beginning a patient education program to correct these problems, the cause must first be established. Typically, the patient who has had a stroke can regain both bowel and bladder control in time. To begin a bladder training program, place the patient on the bedpan or the commode or offer the urinal every 2 hours. Encourage a total fluid intake of at least 2000 mL daily unless contraindicated because of renal or cardiac health problems. A bedside bladder ultrasound is used to check for residual urine after voiding in the early phase of the bladder training program to ensure that the patient is emptying the bladder. Retained urine can lead to a urinary tract infection.

Before establishing a bowel training program, determine the patient's normal time for bowel elimination and any routine that helps promote a stool. This routine is followed, if possible, and the patient is placed on the commode or toilet at the same time as the previous schedule at home. Encourage the patient to drink apple or prune juice and to consume high-fiber foods to help promote bowel elimination. A stool softener (Colace) may be prescribed. Suppositories may also assist in re-establishing a bowel routine. Chapter 8 provides a complete discussion of bowel and bladder training programs.

If the patient has an indwelling urinary catheter, it should be removed as soon as possible to prevent the development of bacteremia and sepsis. The patient with a fever or an older adult who becomes increasingly confused should always be evaluated for a urinary tract infection.

Managing Sensory Perception

Planning: Expected Outcomes. The major concern of patients with sensory or perceptual changes is adapting to neurologic deficits. Therefore the patient with a stroke is expected to adapt to sensory or perceptual changes in vision, proprioception (position sense), and sensation and to be free from injury.

Interventions. Patients with right hemisphere brain damage typically have difficulty with visual-perceptual or spatial-perceptual tasks. They have problems with depth and distance perception and with discrimination of right from left or up from down. Because of these problems, they have difficulty performing routine ADLs. Caregivers help the patient adapt to these disabilities by using frequent verbal and tactile cues and by breaking down tasks into discrete steps.

Always approach the patient from the unaffected side, which should face the door of the room.

Place objects within the patient's field of vision. A mirror may help visualize more of the environment. If the patient has **diplopia** (double vision), a patch may be placed over the affected eye. Remind the nursing staff to ensure a safe environment by removing clutter from the room.

The patient with a left hemisphere lesion generally has memory deficits and may show significant changes in the ability to carry out simple tasks. To assist with memory problems, re-orient the patient to the month, year, day of the week, and circumstances surrounding hospital admission. Establish a routine or schedule that is as structured, repetitious, and consistent as possible. Provide information in a simple, concise manner. A step-by-step approach is often most effective because the patient can master one step before moving to the next. When possible, ask the family to bring in pictures and other familiar objects.

The patient may be unable to plan and execute tasks in an organized manner. **Apraxia**, or the inability to perform previously learned motor skills or commands, may be present. Typically, the patient with apraxia exhibits a slow, cautious, and hesitant behavior style. The physical therapist (PT) assists the patient in compensating for loss of position sense.

Preventing Unilateral Body Neglect

Planning: Expected Outcomes. The patient with stroke is expected to adjust and use techniques to compensate for unilateral (one-sided) body neglect.

Interventions. Unilateral neglect, or neglect syndrome, occurs most commonly in patients who have had a right cerebral stroke. However, it can occur in any patient who experiences hemianopsia, in which the vision of one or both eyes is affected. This problem places the patient at additional risk for injury, especially falls, because of an inability to recognize his or her physical impairment or because of a lack of proprioception (position sense).

Teach the patient to touch and use both sides of the body. For example, encourage the patient to wash both the affected and unaffected sides of the body. When dressing, remind the patient to dress the affected side first. If hemianopsia is present, teach the patient to turn his or her head from side to side to expand the visual field. This scanning technique is also useful when the patient is eating or ambulating.

Community-Based Care

The patient with a stroke may be discharged to home, a rehabilitation center, or a skilled nursing facility (SNF), depending on the extent of the disability and the availability of family or caregiver support. Some patients have no significant neurologic dysfunction and are able to return home and live independently or with minimal support. Other patients are able to return home but require ongoing assistance with ADLs and supervision to prevent accidents or injury. The case or care manager coordinates speech/language, physical, and/or occupational therapy services to continue in the home or on an ambulatory care basis. Patients admitted to a rehabilitation unit/facility or SNF require continued or more complex nursing care as well as extensive physical, occupational, recreational, speech-language, or cognitive therapy, which is coordinated by a case manager. The expected outcome for rehabilitation is to maximize the patient's abilities in all

aspects of life. Some patients who have strokes have severe brain damage. They have profound neurologic impairments and require palliative care.

Home Care Management

Collaborate with the case manager to plan the patient's discharge. Coordinate with rehabilitation therapists to identify needs for assistive or adaptive and safety equipment. The extent of this assessment depends on the patient's disabilities. The home of the patient with hemiparesis should be free from scatter rugs or other obstacles in the walking pathways. The bathtub and toilet should be equipped with grab bars. Anti-skid patches or strips should be placed in the bathtub to prevent slipping. The PT or OT works with the patient and the family or significant others to obtain all needed assistive devices and home modifications *before* the patient is discharged from the hospital, rehabilitation setting, or SNF. Appointments for outpatient speech, physical, and occupational therapy are arranged before discharge for continuing care (per The Joint Commission's National Patient Safety Goals).

Teaching for Self-Management

As part of the discharge process, teach the family about depression that may occur within the 3 months after a stroke. The strongest predictors of post-stroke depression (PSD) are a history of depression, severe stroke, and post-stroke physical or cognitive impairment. Patients may not exhibit typical signs of depression because of their cognitive, physical, and emotional impairments. PSD is associated with increased morbidity and mortality, especially in older men.

The teaching plan for the patient with a stroke also includes drug therapy, ambulation/transfer skills, communication skills, safety precautions, nutritional management, activity levels, and self-management skills. Health teaching should focus on tasks that must be performed by the patient and the family after hospital discharge. Provide both written and verbal instruction in all these areas. Return demonstrations assist in evaluating the family members' competency in tasks required for the patient's care (Fig. 47-5).

The patient must take the prescribed drugs to prevent another stroke and control hypertension. Teach the patient and the family the name of each drug, the dosage, the timing

FIG. 47-5 Son adjusting his mother's wheelchair.

of administration and how to take it, and possible side effects. In collaboration with the PT and OT, teach the patient how to climb stairs safely, if he or she is able; transfer from the bed to a chair; get into and out of a car; and use any aids for mobility. The patient and family members are also taught how to use any equipment needed to increase independence in self-management skills. Provide important information regarding what to do in an emergency and whom to call for nonemergency questions.

Families may feel overwhelmed by the continuing demands placed on them. Depending on the location of the lesion, the patient may be anxious, slow, cautious, and hesitant and lack initiative (left hemisphere lesions) or he or she may be impulsive and seemingly unaware of any deficit. Family members and other caregivers need to spend time away from the patient on a routine basis to continue to provide full-time care without sacrificing their own physical and emotional health. Refer the family to social services or other community resources for further support, counseling, and possible respite care.

Health Care Resources

Available resources include a variety of publications from the American Heart Association (www.americanheart.org), including *Stroke: A Guide for Families* and *Stroke: Why Do They Behave That Way?* The National Stroke Association (www.stroke.org) also provides publications and videotapes for caregivers and patients. *Recovering After a Stroke: A Patient and Family Guide* is available from the Agency for Healthcare Research and Quality (www.ahrq.gov). Refer the patient and family members or significant others to local stroke support groups.

For patients who require palliative end-of-life care, refer the family to hospice care. **Chapter 9** gives a detailed description of end-of-life care and advance directives.

EVALUATION: OUTCOMES

Evaluate the care of the patient with stroke based on the identified priority patient problems. The expected outcomes are that the patient:

- Has an adequate blood flow through the cerebral vasculature to maintain brain function
- Ambulates and performs self-care independently, with or without assistive devices
- Learns to adapt to sensory and perceptual changes
- Adjusts and uses techniques to compensate for one-sided neglect
- Communicates effectively or develops strategies for effective communication
- Has adequate nutrition and avoids aspiration
- Controls elimination of urine and stool

TRAUMATIC BRAIN INJURY

Pathophysiology

A head injury is caused by a blow or jolt to the head or by penetration of the head by a bullet or other foreign object. As a result, the normal functioning of the brain is disrupted. Regardless of the severity of injury, the patient may have short-term or long-term physical, cognitive, financial, and emotional consequences.

Various terms are used to describe the brain injuries that occur when a mechanical force is applied either directly or indirectly to the brain. A force produced by a blow to the head is a *direct* injury, whereas a force applied to another body part with a rebound effect to the brain is an *indirect* injury. The brain responds to these forces by movement within the rigid cranial vault. It may also rebound or rotate on the brainstem, causing diffuse axonal injury (shearing injuries). The brain may be contused (bruised) or lacerated/torn as it moves over the inner surfaces of the cranium, which are irregularly shaped and sharp. Damage most commonly occurs to the frontal and temporal lobes.

Movement or distortion within the cranial cavity is possible because of multiple factors. The first factor is how the brain is supported by cerebrospinal fluid (CSF) within the cranial cavity. When external force is applied to the head, the brain can be injured by the internal surfaces of the skull and meninges. The second factor is the consistency of brain tissue, which is very fragile and prone to injury. Brain injury can also be categorized as primary or secondary.

Primary Brain Injury

Primary brain damage occurs at the time of injury and results from the physical stress (force) within the tissue caused by open or closed trauma. An **open head injury** occurs when the skull is fractured or when it is pierced by a penetrating object. The integrity of the brain and the dura is violated, and there is exposure to environmental contaminants. Damage may occur to the underlying vessels, dural sinus, brain, and cranial nerves. A **closed head injury** is the result of blunt trauma; the integrity of the skull is not violated. It is the more serious of the two types of injury, and the damage to brain tissue depends on the degree and mechanisms of injury.

Brain injury may also be described as mild, moderate, or severe. A Glasgow Coma Scale (GCS) score of 13 to 15 and a loss of consciousness for up to 15 minutes reflect a *mild traumatic brain injury (TBI)* (MTBI). A *moderate TBI* often includes a period of loss of consciousness (LOC) up to 6 hours and may occur with other systemic injury and a GCS score of 9 to 12. A short critical care stay may be needed for close monitoring. After injury, these patients may have difficulty with work, learning, and role function. *Severe head injury* (GCS score of 3 to 8 and loss of consciousness for longer than 6 hours) is more serious and requires management in critical care with ongoing monitoring of hemodynamic stability and intracranial pressure (ICP).

The incidence of *minor* head injuries is difficult to estimate because most are not reported. However, they account for most of all diagnosed head injuries. Often patients do not seek medical care because they deny that anything is wrong, do not have any health insurance, or may feel guilty or embarrassed over the circumstances of the injury.

Symptoms include a wide array of physical and cognitive problems that range from persistent headache, dizziness, and drowsiness to other symptoms listed on **Chart 47-7**. These symptoms usually resolve within 72 hours. In some cases the symptoms persist and may last days, weeks, or months. For other patients, severe physical and cognitive problems remain despite relatively mild initial symptoms and normal diagnostic test findings. This cluster of symptoms is also referred to as *post-concussion syndrome*.

CHART 47-7 KEY FEATURES

Traumatic Brain Injury

- Amnesia (loss of memory)
- Headache
- Dizziness
- Seizure
- Loss of consciousness or sleepiness/drowsiness
- Restlessness or irritability
- Disorientation or confusion
- Scalp bruising and tenderness
- Personality changes
- Diplopia
- Gait changes
- Severe head injury:
 - Pupil changes
 - Bradycardia
 - Papilledema
 - High blood pressure/widened pulse pressure
 - Hypotension and tachycardia (hypovolemic shock)
 - Nuchal rigidity (cerebrospinal fluid [CSF] leak)

Open Head Injury. The types of fractures associated with an open head injury are linear, depressed, open, and comminuted. A **linear fracture** is a simple, clean break in which the impacted area of bone bends inward and the area around it bends outward. Linear fractures are the most common type of skull fracture. In a **depressed fracture**, the bone is pressed inward into the brain tissue to at least the thickness of the skull. In an **open fracture**, the scalp is lacerated, creating a direct opening to the brain tissue. A **comminuted fracture** involves fragmented bone with depression into the brain tissue.

A unique fracture is a **basilar skull fracture**. It occurs at the base of the skull, usually extending into the anterior, middle, or posterior fossa, and results in cerebrospinal fluid (CSF) leakage from the nose or ears. This fracture has the potential for hemorrhage caused by damage to the internal carotid artery; damage to cranial nerves (CNs) I, II, VII, and VIII; and infection.

Most penetrating injuries to the skull are caused by gunshot wounds (GSWs) and knife injuries. The degree of injury to brain tissue depends on the velocity (speed), mass, shape, and direction of impact. High-velocity injuries produce the greatest damage to brain tissue. As with any open head injury, the patient with a penetrating injury is at high risk for infection from the object that pierced the skull and from other environmental contaminants.

Closed Head Injury. Closed head injuries are caused by blunt trauma and lead to concussions, contusions, and lacerations of the brain. A **contusion** is a bruising of the brain tissue and is most commonly found at the site of impact (coup injury) or in a line opposite the site of impact (**contrecoup injury**) (Fig. 47-6). The base of the frontal and temporal lobes is most often involved. A **concussion** is a shaky movement of the brain and may be mild or more severe. Some patients lose consciousness for a short time.

The damage to the brain may be mild, as occurs in a concussive injury, or it may be more severe, causing diffuse axonal injury or widespread injury to the white matter of the brain. **Diffuse axonal injury (DAI)** is usually related to

FIG. 47-6 Coup (site of impact) injury to frontal area of brain, and contrecoup injury to frontal and temporal areas of the brain.

high-speed acceleration/deceleration, typically seen in motor vehicle crashes. In this injury, significant damage occurs to axons in the white matter. Damage may also be found in the corpus callosum, midbrain, cerebellum, and upper brainstem. Depending on severity, small areas of hemorrhage and enlargement of the lateral ventricles may be seen on computed tomography (CT). Severe DAI may present with immediate coma, and most survivors require long-term care.

A **laceration** causes actual tearing of the cortical surface vessels, which may lead to secondary hemorrhage and significant cerebral edema and inflammation. This condition is more serious than a contusion.

Types of Force

Other factors that must be considered in the dynamics of head injury are the type of force and the mechanisms of injury involved. An **acceleration** injury is caused by an external force contacting the head, suddenly placing the head in motion. A **deceleration** injury occurs when the moving head is suddenly stopped or hits a stationary object (Fig. 47-7). These forces may be sufficient to cause the cerebrum to rotate about the brainstem, resulting in shearing, straining, and distortion of the brain tissue, particularly of the axons in the brainstem and cerebellum. Small areas of hemorrhage may develop around the blood vessels that sustain the impact of these forces (stress), with destruction of adjacent brain tissue. Particularly affected are the basal nuclei and the hypothalamus.

Secondary Injury

Secondary injury to brain injury includes any processes that occur *after* the initial injury and worsen or negatively influence patient outcomes. They result from physiologic,

FIG. 47-7 Head movement during acceleration-deceleration injury, which is typically seen in motor vehicle crashes.

vascular, and biochemical events that are an extension of the primary injury and involve cellular changes that contribute to tissue injury. The most common responses are hypotension, hypoxia, ischemia, and cerebral edema. Damage to the brain tissue occurs primarily because the delivery of oxygen and glucose to the brain is interrupted.

Increased Intracranial Pressure. The cranial contents include brain tissue, blood, and cerebrospinal fluid (CSF). These components are encased in the relatively rigid skull. Within this space, there is little room for any of the components to expand or increase in volume. Through the processes of accommodation and compliance, ICP is maintained at its normal level of 10 to 15 mm Hg despite periodic increases in pressure that occur with straining during defecation, coughing, or sneezing. Any increase in the volume of one component must be compensated for by a decrease in the volume of one of the other components.

As a first response to an increase in the volume of any of these components, the CSF is shunted or displaced from the cranial compartment to the spinal subarachnoid space or the rate of CSF absorption is increased. An additional response, if needed, is a decrease in cerebral blood volume by movement of cerebral venous blood into the sinuses. As long as the brain can compensate for the increase in volume and remain compliant, increases in ICP are minimal.

Increased ICP is the leading cause of death from head trauma in patients who reach the hospital alive. It occurs when

compliance no longer takes place and the brain cannot accommodate further volume changes. As ICP increases, cerebral perfusion decreases, leading to tissue hypoxia, a decrease in serum pH level, and an increase in the level of carbon dioxide. This process causes cerebral vasodilation, edema, and a further increase in ICP, and the cycle continues. If the condition remains untreated, the brain may herniate downward toward the brainstem or laterally from a unilateral lesion within one cerebral hemisphere, causing irreversible brain damage and possibly death (**brain herniation syndromes**).

Two types of edema may cause increased ICP: vasogenic edema and cytotoxic edema. A third type (interstitial edema) occurs in the presence of acute brain swelling. *Vasogenic* edema is seen most often as a cause of increased ICP in the adult. It involves an increase in the volume of brain tissue. This increase is caused by an abnormal permeability of the walls of the cerebral vessels, which allows protein-rich plasma infiltrate to leak into the extracellular space of the brain. The fluid collects primarily in the white matter.

Cytotoxic, or cellular, edema may occur as a result of a hypoxic insult, which causes a disturbance in cellular metabolism, the sodium pump, and active ion transport. The brain is quickly depleted of available oxygen, glucose, and glycogen and converts to anaerobic metabolism. The sodium pump fails, and sodium enters the cells and pulls water from the extracellular space. The serum sodium level decreases to less than 120 mEq/L (hyponatremia). As a result, an abnormal accumulation of fluid in the brain cells and a decrease in the extracellular fluid space occur. Cytotoxic edema may lead to vasogenic edema and a further increase in ICP.

Interstitial edema occurs with acute brain swelling and is associated with elevated blood pressure or increased CSF pressure. Edema develops rapidly in the perivascular and periventricular white space and can be controlled through measures to reduce blood pressure, decrease CSF pressures, or increase the **cerebral perfusion pressure (CPP)**. The CPP is the pressure gradient over which the brain is perfused. It is influenced by oxygenation, cerebral blood volume, blood pressure, cerebral edema, and ICP and is determined by subtracting the mean ICP from the mean arterial pressure. *Maintenance of a CPP above 70 mm Hg is generally accepted as an expected outcome of therapy.*

Hemorrhage. Hemorrhage, which causes a brain hematoma (collection of blood) or clot, may occur as part of the primary injury and begin at the moment of impact. It may also arise later from vessel damage. Classically, bleeding is caused by vascular damage from the shearing force of the trauma or direct physical damage from skull fractures or penetrating injury. *All hematomas are potentially life threatening because they act as space-occupying lesions and are surrounded by edema.* Three major types of hemorrhage after TBI are **epidural**, **subdural**, and **intracerebral hemorrhage**. Subarachnoid hemorrhage may also occur.

An **epidural hematoma** results from arterial bleeding into the space between the dura and the inner skull (Fig. 47-8). It is often caused by a fracture of the temporal bone, which houses the middle meningeal artery. Patients with epidural hematomas have “lucid intervals” that last for minutes during which time the patient is awake and talking. This follows a momentary unconsciousness that occurs within minutes of the injury.

FIG. 47-8 Epidural hematoma (outside the dura mater of the brain), subdural hematoma (under the dura mater), and intracerebral hemorrhage (within the brain tissue).

! NURSING SAFETY PRIORITY

Critical Rescue

After the initial interval, symptoms progress very quickly with potentially life-threatening ICP elevation and structural changes. Monitor the patient suspected of epidural bleeding frequently (every 5-10 minutes) for changes in neurologic status. The patient can become quickly and increasingly symptomatic and lose consciousness. *An epidural hematoma is a neurosurgical emergency!* Notify the health care provider or Rapid Response Team immediately if these changes occur. Carefully document your assessments and the patient's overall condition.

A **subdural hematoma (SDH)** results from venous bleeding into the space beneath the dura and above the arachnoid (see Fig. 47-8). It occurs most often from a tearing of the bridging veins within the cerebral hemispheres or from a laceration of brain tissue. Bleeding from this injury occurs more slowly than from an epidural hematoma. SDHs are subdivided into acute, subacute, and chronic. An acute SDH presents within 48 hours after impact; the subacute SDH, between 48 hours and 2 weeks; and the chronic SDH, from 2 weeks to several months after injury. SDHs have the highest mortality rate because they often are unrecognized until the patient presents with severe neurologic compromise.

An intracerebral hemorrhage (ICH) is the accumulation of blood within the brain tissue caused by the tearing of small arteries and veins in the subcortical white matter (see Fig. 47-8). It often acts as a space-occupying lesion and may be potentially devastating, depending on its location. ICH may also produce significant brain edema and ICP elevations. A brainstem hemorrhage occurs as a result of direct trauma, fractures, or torsion injuries to the brainstem. Brainstem injuries have a very poor prognosis.

Hydrocephalus. Hydrocephalus is an abnormal increase in CSF volume. It may be caused by impaired reabsorption of CSF at the arachnoid villi (from subarachnoid hemorrhage or meningitis), called a **communicating hydrocephalus**. It may also be caused by interference or blockage with CSF outflow from the ventricular system (from cerebral edema, tumor, or debris). The ventricles may dilate from the relative increase in CSF volume. Ultimately, if not treated, this increase may lead to increased ICP.

Brain Herniation. In the presence of increased ICP, the brain tissue may shift and herniate downward. Of the several types of herniation syndromes (Fig. 47-9), uncal herniation is one of the most clinically significant because it is life threatening. It is caused by a shift of one or both areas of the temporal lobe, known as the **uncus**. This shift creates pressure on the third cranial nerve. Late findings include dilated and non-reactive pupils, ptosis (drooping eyelids), and a rapidly deteriorating level of consciousness. Central herniation is caused by a downward shift of the brainstem and the diencephalon from a supratentorial lesion. It is clinically manifested by Cheyne-Stokes respirations, pinpoint and nonreactive pupils, and potential hemodynamic instability. All herniation syndromes are potentially life threatening, and the physician must be notified immediately when they are suspected.

Etiology

The most common causes of traumatic brain injury (TBI) in the United States are falls and motor vehicle crashes. In many cases, alcohol and drugs are contributing factors to the event. Acts of violence and sports-related injuries are the next most common causes. The United States is seeing increasing numbers of survivors of head injury from wartime blast injuries. Preventive measures to avoid TBI have also been developed.

FIG. 47-9 Herniation syndromes.

Incidence/Prevalence

Each year over a million people in the United States have some type of TBI. Of these, many require hospitalization and some die. Summer and spring months, evenings, nights, and weekends are associated with the greatest number of injuries. Young males are more likely than young females to have a TBI. Men tend to play more sports, take more risks when driving, and consume larger amounts of alcohol than women. Falls occur most often in older adults, especially older women who have osteoporosis.

Health Promotion and Maintenance

Prevention of falls is particularly important, especially for older adults. People need to be aware of environmental factors that may increase the likelihood of falls such as throw rugs and inadequate lighting. When possible, they should have safety equipment installed in bathtubs and showers. Remind them that balance and coordination may decrease as a result of aging.

Nurses should educate the public on ways to decrease the incidence of TBI by using safe practices such as wearing seat belts. Helmets should be used for skateboarding and bicycle and motorcycle riding. Teach the importance of following driving laws to avoid speeding and other violations.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Obtaining an accurate history from a patient who has sustained a TBI may be difficult because of either the seriousness of the injury or the presence of **amnesia** (loss of memory). It is not unusual for the patient to experience amnesia for the events before or after the injury. The patient with a serious head injury is often admitted to the hospital unconscious or in a confused and combative state. If the patient cannot

provide information, the history can be obtained from first responders or witnesses to the injury. Always ask when, where, and how the injury occurred. Did the patient lose consciousness; if so, for how long? Has there been a change in the level of consciousness (LOC)? If trauma is related to drug or alcohol consumption, it may be difficult to differentiate neurologic changes from head trauma from those produced by intoxication.

Obtain as much information about the events as possible immediately after the injury. Patients with a severe injury may have several different presentations. The patient may be completely unresponsive after the injury. Or, the patient may first be responsive and neurologically deteriorate rapidly within a few minutes to several hours. In another typical presentation, the patient is unconscious for a few minutes as a result of the primary brain injury, returns to a normal level of consciousness, and then rapidly deteriorates from secondary insult to the brain.

Determine whether the patient had any seizure activity before or after the injury and whether there is a history of a seizure disorder. Obtain precise information about the circumstances of falls, particularly in the older patient (**Chart 47-8**). Other pertinent information includes hand dominance, any diseases of or injuries to the eyes, and any allergies to drugs or food, particularly seafood. People allergic to seafood are often allergic to the IV contrast media used in diagnostic tests. Inquire about a history of alcohol or drug use and abuse because these substances may mask the symptoms of increased ICP. The Joint Commission and the Centers for Medicare and Medicaid Services (CMS) require that all patients be screened for abuse and neglect when they are admitted to any type of health care facility.

Physical Assessment/Clinical Manifestations

No two injuries are alike. The patient with a TBI may have a variety of manifestations depending on the severity of injury and the resulting increase in intracranial pressure (ICP) (see **Chart 47-6**). Underlying neurologic problems may

CHART 47-8 NURSING FOCUS ON THE OLDER ADULT

Head Injury

- Head injury is the fifth leading cause of death in older adults.
- The 65- to 75-year age-group has second highest incidence of head injury of all age-groups.
- Falls and motor vehicle crashes are the most common causes of head injury.
- Factors that contribute to high mortality are:
 - Falls causing subdural hematomas (closed head injuries), especially chronic subdural hematomas
 - Poorly tolerated systemic stress, which is increased by admission to a high-stimuli environment
 - Medical complications, such as hypotension, hypertension, and cardiac problems
 - Decreased protective mechanisms, which make patients susceptible to infections (especially pneumonia)
 - Decreased immunologic competence, which is further diminished by head injury

be masked by drugs or alcohol. Assess for signs of increased ICP, including hypotension, hypoxemia (decreased blood level of oxygen), or **hypercapnia** (increased blood level of carbon dioxide). The early detection of subtle changes in the patient's neurologic status enables the health care team to prevent or treat potentially life-threatening complications.

Airway and Breathing Pattern Assessment. *The first priority is the assessment of the patient's ABCs—airway, breathing, and circulation.* Because TBI is associated with cervical spinal cord injuries, all patients with head trauma are treated as though they have cord injury until x-ray studies prove otherwise. *Older adults are especially prone to cervical injuries at the first or second vertebral level, a life-threatening problem.* Assess for indicators of spinal cord injury, such as loss of motor and sensory function, tenderness along the spine, and abnormal head tilt.

! NURSING SAFETY PRIORITY

Critical Rescue

The upper cervical spinal nerves innervate the diaphragm to control breathing. Monitor TBI patients for respiratory problems and diaphragmatic breathing, as well as diminished or absent reflexes. Although hypoxia and hypercapnia are best detected through SaO_2 and end-tidal volume carbon dioxide measurement, observe chest wall movement and listen to breath sounds. Report any sign of respiratory problems immediately to the physician!

In some cases, an endotracheal tube is inserted for mechanical ventilation. Injuries to the brainstem may cause a change in the patient's breathing pattern, such as Cheyne-Stokes respirations, central neurogenic hyperventilation, and/or apnea.

Vital Signs Assessment. The mechanisms of autoregulation are often impaired as the result of a TBI. The more serious the injury, the more severe is the impact on autoregulation. Monitor the patient's blood pressure and pulse to detect possible changes in cerebral blood flow. The patient may have hypotension or hypertension. **Cushing's triad**, a classic but late sign of increased ICP, is manifested by severe hypertension with a widened pulse pressure and bradycardia.

As ICP increases, the pulse becomes thready, irregular, and rapid. Cerebral blood flow increases in response to hypertension. Vasogenic edema may occur, further increasing ICP.

Hypotension and tachycardia suggest hypovolemic shock. This decrease in blood volume may lead to decreased cerebral perfusion pressure and eventually to ischemia and infarction of the brain tissue. Hypovolemic shock is usually due to intra-abdominal bleeding or bleeding into the soft tissue around major fractures—not to intracranial bleeding. Cardiac dysrhythmias may result from chest trauma, bruising of the heart, or interference with the autonomic nervous system. They may also result from severe ICP elevations and brainstem pressure.

Neurologic Assessment. Many hospitals use the Glasgow Coma Scale or other assessment tool to document neurologic status (see Fig. 43-10 in Chapter 43). *The most important variable to assess is LOC!* A decrease or change in LOC is typically the first sign of deterioration in neurologic status. Changes in consciousness or orientation are due to injury to the cerebral cortex and may also involve damage to the reticular formation. A decrease in arousal or increased sleepiness and coma are caused by pressure on the reticular activating system within the brainstem. *Early indicators of a change in LOC include behavior changes (e.g., restlessness, irritability) and disorientation, which are often subtle in nature.*

Ask about previous eye injury or drugs that affect pupillary dilation and constriction, such as anticholinergics and adrenergics.

! NURSING SAFETY PRIORITY

Critical Rescue

Check pupils of TBI patients for size and reaction to light. Report and document any changes in pupil size, shape, and reactivity to the health care provider immediately because they could indicate an increase in ICP.

Pupillary changes or eye signs differ depending on which areas of the brain are damaged. *Pinpoint and nonresponsive pupils are indicative of brainstem dysfunction at the level of the pons.* Of particular importance is the **ovoid pupil**, which is regarded as the midstage between a normal-size pupil and a dilated pupil. In some agencies, a portable automated pupillometer is used to measure pupil size and reaction rather than manual examination.

Asymmetric (uneven) pupils, loss of light reaction, or unilateral or bilateral dilated pupils are treated as herniation of the brain from increased ICP until proven differently. *Pupils that are fixed (nonreactive) and dilated are a poor prognostic sign, resulting from a marked increase in ICP. Patients with this problem are sometimes referred to as having "blown" pupils.*

Check gross vision if the patient's condition permits. Have the patient read any printed material (e.g., your name tag) or count the number of fingers that you hold within the patient's visual field. Loss of vision is usually caused by injury to the occipital lobe, which produces temporary cortical blindness.

If the patient can participate, the health care provider or neurosurgical nurse tests *cranial nerves* (CNs) III, IV, and VI. Extraocular movements may be diminished because of increased ICP and hydrocephalus. Damage to the

optic chiasm or optic tract may cause visual-field deficits or **diplopia** (double vision). In the unconscious patient, additional oculocephalic and oculovestibular tests are performed to test the integrity of the brainstem and of CNs III, VI, and VII.

Monitor for additional late signs of increased ICP. These manifestations include severe headache, nausea, vomiting (often projectile), seizures, and papilledema (seen by ophthalmoscopic examination). **Papilledema**, also known as a **choked disc**, is edema and hyperemia (increased blood flow) of the optic disc. It is always a sign of increased ICP. Headache and seizures are a response to the injury and may or may not be associated with increased ICP. Always remember that the patient with a head injury is at risk for potentially devastating ICP elevations hours or a few days after the event!

Assess for bilateral motor responses. The patient's motor loss or dysfunction usually appears contralateral (opposite side) to the site of the lesion, similar to a stroke. For example, a left-sided hemiparesis reflects an injury to the right cerebral hemisphere. A deterioration in motor function or the development of abnormal posturing (**decerebrate** or **decorticate posturing**) or flaccidity is another indicator of increased ICP (see Fig. 43-11 in Chapter 43). These changes are due to dysfunction within the pyramidal (motor) tracts of the spinal cord. Assess for brainstem or cerebellar injury, which may cause **ataxia** (loss of balance), decreased or increased muscle tone, and weakness. Remember that changes in motor function may also be an indicator of a spinal cord injury.

Carefully observe the patient's ears and nose for any signs of cerebrospinal fluid (CSF) leaks that result from a basilar skull fracture. CSF placed on a white absorbent background can be distinguished from other fluids by the "halo" sign, a yellowish stain surrounded by bloody drainage. If it is present, it tests positive for glucose when a strip testing method (dipstick) is used. However, this method of determining a CSF leak is not always reliable. If there is a CSF leak, assess for **nuchal rigidity** (stiff neck), which may indicate infection or blood in the CSF. Nuchal rigidity is not checked until a spinal cord injury has been ruled out.

Palpate the patient's head carefully to detect the presence of fractures or hematomas. Look for areas of ecchymosis (bruising), tender areas of the scalp, and lacerations.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

An alert and oriented client is admitted to the emergency department with a moderate head injury. Which assessment finding will the nurse report immediately to the health care provider?

- A. Headache
- B. Slight dizziness
- C. Fatigue
- D. Sudden drowsiness

Psychosocial Assessment

Patients with a mild head injury may still have symptoms of disability 1 year or longer after injury. Long-term effects are not common. The person who has had a moderate or severe head injury, however, is never the same as before the injury. These patients have varying degrees of personality changes manifested by temper outbursts, depression, risk-taking behavior, and denial of disability. They may become talkative

and develop a very outgoing personality. Memory, especially recent or short-term memory, is affected and should not be confused with problems of aphasia. The ability to learn new information and concentration may be affected. The patient may have problems with insight and planning. All these problems may lead to difficulties within the family structure and with social and work-related interactions. Assess coping strategies that have been used in the past to determine the patient's ability to adapt to the changes in physical and cognitive abilities.

Assess family dynamics, particularly if the patient is discharged to the family's care directly from the acute care hospital. The family or significant others must also cope with changes in the patient's physical appearance and cognitive abilities. Many families become angry with the patient for being injured, especially when his or her behavior or their own behavior resulted in an injury that could have been prevented. They may feel guilty that they did not or were not able to prevent the injury. The family or significant others may feel overwhelmed by the complexity of care required and the long recovery period. Help both the family and the patient develop coping strategies to deal with the potential role reversals and role changes caused by the injury.

Laboratory Assessment

There are no laboratory tests to diagnose a primary brain injury. However, several laboratory tests are used to diagnose or indicate measures to prevent secondary brain insult. The health care provider requests arterial blood gases, complete blood count (CBC), and serum glucose and electrolyte levels. These tests are performed to monitor hemodynamic status, identify electrolyte imbalance, and detect infection. Severe electrolyte imbalances can also contribute to secondary injury, as well as increase the risk for seizures. A toxicology screen and an electrocardiogram (ECG) are often requested.

Imaging Assessment

The health care provider immediately requests computed tomography (CT) scanning to identify the extent and scope of injury to the brain. This diagnostic test can identify the presence of a lesion that requires surgical intervention, such as an epidural or subdural hematoma. Radiography and CT scanning of the cervical spine and the skull are done to rule out fractures and dislocations. A chest x-ray is done to identify fractured ribs or other chest injuries. An abdominal ultrasound or CT may be obtained to assist in the diagnosis of abdominal bleeding or bowel laceration.

Magnetic resonance imaging (MRI) is particularly useful in the diagnosis of diffuse axonal injury, but it is not recommended for patients with ICP or other invasive monitoring devices.

Other Diagnostic Assessment

As the patient's condition stabilizes, the physician may request other diagnostic tests to identify the extent of injury to the brain. For example, the integrity of the cerebral vessels is measured through the use of Doppler flow studies or an arteriogram. Cerebral perfusion is measured by cerebral blood flow studies. Evoked potentials provide information on the functioning sensory pathways and may be useful in predicting outcome.

INTERVENTIONS

The patient with a *severe* head injury is admitted to the critical care unit or a trauma center. Patients with *moderate* head injuries are admitted to either the general nursing unit or the critical care unit, where they are closely observed for at least 24 hours. Those with *mild* TBI may possibly be sent home from the emergency department with instructions.

Nonsurgical Management

As with any critically injured patient, priority is given to maintaining a patent airway, breathing, and circulation. Specific nursing interventions for the patient with a head injury are directed toward preventing or detecting increased ICP, promoting fluid and electrolyte balance, and monitoring the effects of treatments and drug therapy. Providing health teaching and emotional support for the patient and family is a vital part of the plan of care.

Preventing and Detecting ICP. Take and record the patient's *vital signs* every 1 to 2 hours or more often based on patient acuity. The health care provider may prescribe drug therapy to prevent severe hypertension or hypotension. The patient in the critical care unit is connected to a cardiac monitor to detect any cardiac dysrhythmias. Nonspecific ST-segment or T-wave changes may occur, possibly in response to stimulation of the autonomic nervous system or an increase in the level of circulating catecholamines such as epinephrine. Document and report cardiac irregularities to the health care provider.

The patient with a head injury is often admitted with a fever—a defense mechanism in the presence of trauma or an indication of inflammatory response. Fever as a consequence of infection may develop later in the course of the disease. A third cause of fever is a central fever caused by hypothalamic damage. It is manifested by an absence of sweating and no diurnal (night and day) variation. This type of fever is high and lasts several days to weeks. In addition, it responds better to cooling (e.g., hypothermia blanket, sponge bath) than to the administration of antipyretic drugs such as acetaminophen (Tylenol, Ace-Tabs ). *Fever from any cause is associated with higher morbidity and mortality rates.*

Prophylactic *hyperventilation* during the first 20 hours after injury is usually avoided because it may produce ischemia by causing cerebral vasoconstriction. The result is a decrease in cerebral blood volume and ICP. In acute neurologic deterioration, however, it may be used for brief periods of ICP elevations.

The patient who requires mechanical breathing assistance is ventilated to maintain a partial pressure of arterial carbon dioxide (P_{aCO_2}) of about 35 to 38 mm Hg. One major outcome is to prevent increased carbon dioxide. *Carbon dioxide is a very potent vasodilator that can contribute to increases in ICP. Arterial oxygen levels (P_{aO_2}) are maintained between 80 and 100 mm Hg to prevent cerebral vasodilation resulting from hypoxemia. Monitor arterial blood gas values at least twice daily and after each change in the ventilator setting.*

Pulmonary secretions tend to pool as the result of a decreased LOC, ineffective cough, or altered breathing pattern. The secretions may be thick because of the diuretics or fluid intake restriction that may be used to prevent cerebral edema. Collaborate with the respiratory therapist to provide chest physiotherapy as needed based on patient assessment. Pay close attention to the ICP response.

Carefully observe the patient with increased ICP when suctioned. If the patient is intubated, manually hyperventilate him or her with 100% oxygen before each pass of the catheter. Overly aggressive hyperventilation with endotracheal suctioning may be dangerous, though, because of the cerebral vasoconstriction caused by even transient hypocapnia (low arterial carbon dioxide levels). This may increase the risk for cerebral ischemia as a secondary event. Allow the patient to rest a few minutes after suctioning to prevent increased ICP. Lidocaine given IV or endotracheally may be used to suppress the cough reflex; coughing increases ICP.

! NURSING SAFETY PRIORITY

Action Alert

Position the TBI patient to avoid extreme flexion or extension of the neck and to maintain the head in the midline, neutral position. Log roll the patient during turning to avoid extreme hip flexion, and keep the head of the bed elevated at least 30 degrees or as recommended by the health care provider.

Head positioning should be based on both intracranial pressure (ICP) and systemic blood pressure. If increasing head elevation lowers ICP but also significantly lowers systemic blood pressure, the patient does not benefit and may actually be harmed. Base head elevation on cerebral perfusion pressure when possible. Carefully position the head of the bed in the older patient. The dura is tightly adhered to the skull and may pull away from the brain, leading to a subdural hematoma.

Patients with *severe* TBI often die. As the deterioration begins, keep in mind that the patient may be a potential organ donor. *Before* brain death is declared, contact the local organ procurement organization. Determine if the patient consented to be an organ donor. This information is typically on a driver's license or other state-issued card or advance directive. The patient's wishes should be followed unless he or she has a medical condition that prevents organ donation. The physician discusses the severity of the patient's condition and the possibility of organ donation with the family. Some families may not agree with the patient's decision, which can cause an ethical dilemma. Health care agencies have ethics committees that can help with these situations.

Determining Brain Death. In 2010, the American Academy of Neurology guidelines for determining brain death were updated. Four prerequisites must be met to establish a brain death diagnosis (Wijdicks et al., 2010):

- Coma of known cause as established by history, clinical examination, laboratory testing, and neuroimaging
- Normal or near-normal core body temperature (higher than 36° C)
- Normal systolic blood pressure (higher than or equal to 100 mm Hg)
- At least one neurologic examination (some states and health care systems require two)

No consensus has been reached on who is qualified to perform head-to-toe brain death neurologic examinations, but neurologists and critical care intensivists typically do them. Neuroimaging tests are not required to confirm brain death but are desirable. Example of tests that may be done include cerebral angiography, bedside electroencephalography (EEG), and cerebral computed tomographic angiography. There is

no evidence that new tests like cerebral MRI are better at determining death and may cause a risk for bias in identifying death (Hills, 2010).

Drug Therapy. *Glucocorticoids* (dexamethasone [Decadron, Dexasone] and methylprednisolone sodium succinate [Solu-Medrol, Medrol]) have no benefit in the management of increased ICP as a result of head injury or cerebral infarction. Instead, mannitol (Osmitol), an osmotic diuretic, is used to treat cerebral edema by pulling water out of the extracellular space of the edematous brain tissue. It is most effective when given in boluses rather than as a continuous infusion. Furosemide (Lasix), a loop diuretic, is often used as adjunctive therapy to reduce the incidence of rebound from mannitol. It also enhances the therapeutic action of mannitol, reduces edema and blood volume, decreases sodium uptake by the brain, and decreases the production of CSF at the choroid plexus.

Administer *mannitol* through a filter in the IV tubing or, if given by IV push, draw it up through a filtered needle to eliminate microscopic crystals. For the patient receiving either osmotic or loop diuretics, monitor for intake and output, severe dehydration, and indications of acute renal failure, weakness, edema, and changes in urine output. Serum electrolyte and osmolality levels are measured every 6 hours. Mannitol is used to obtain a serum osmolality of 310 to 320 mOsm/L, depending on physician preference and the desired outcome of therapy. Insert an indwelling urinary catheter to maintain strict measurement of output. Check the patient's serum and urine osmolality daily.

Opioids such as morphine sulfate or fentanyl may be used with ventilated patients to decrease agitation and control restlessness if the agitation is caused by pain. Fentanyl has fewer effects on blood pressure and heart rate than morphine and may therefore be a safer agent to manage pain. These agents may be reversed with naloxone (Narcan), but opioid reversal should be avoided if at all possible to reduce risk for withdrawal and rebound pain and agitation. Sedatives such as lorazepam (Ativan) and midazolam (Versed) may be used for anxiety to promote comfort and treat agitation. Sedatives and opioids may mask the neurologic assessment and potentially lower blood pressure. Therefore they should be administered in small incremental doses to a predetermined endpoint with close assessment of hemodynamic stability and neurologic status.

Antiepileptic drugs, such as phenytoin (Dilantin), to prevent seizures that occur initially more than 7 days (**late-onset seizures**) after injury are not recommended. However, they may be recommended as an option to prevent seizure activity that may occur within 7 days after injury (**early-onset seizures**). Acetaminophen (Tylenol, Ace-Tabs ♣) and aspirin (acetylsalicylic acid [ASA], Ancasal ♣) are given to patients who are febrile (temperature greater than 101° F [38.3° C]) to reduce fever.

Inducing Barbiturate Coma. *Barbiturate coma* (coma induced by barbiturates) has been used for intracranial hypertension (increased ICP) that cannot be controlled by other means. Either pentobarbital sodium (Nembutal, Novopentobarb ♣) or thiopentone is the drug of choice. These drugs decrease the metabolic demands of the brain and cerebral blood flow, stabilize cell membranes, decrease the formation of vasogenic edema, and produce a more uniform blood supply. The health care provider adjusts the dosage to

maintain complete unresponsiveness. As a consequence, it is difficult to recognize subtle or obvious neurologic changes. The patient requires mechanical ventilation, sophisticated hemodynamic monitoring, and ICP monitoring. Complications of barbiturate coma include decreased GI motility, cardiac dysrhythmias from hypokalemia, hypotension, and fluctuations in body temperature.

Maintaining Fluid and Electrolyte Management. The patient with TBI is at risk for diabetes insipidus (DI) and the syndrome of inappropriate antidiuretic hormone (SIADH) because the pituitary gland may be injured or compressed from cerebral edema (see Chapter 65). In the patient with multiple trauma, fluid overload can occur and cerebral edema can worsen from the rapid administration of IV fluids or plasma expanders. Fluid management may be titrated to optimize volume resuscitation but minimize brain swelling and ICP elevation. ICP is also influenced by the response to diuretic therapy and laboratory values. Check urine specific gravity every 1 to 4 hours. Monitor serum and urine osmolality and electrolytes at least daily.

Managing Nutritional Status. The patient with a *major* head injury after the acute phase of management may have changes in these areas:

- Sense of smell
- Ability to taste, swallow, or feel the presence of food within the oral cavity
- Vision, pain, and temperature sensation

As a result, he or she is at risk for nutritional deficits that may interfere with the healing process.

The patient who is moderately to severely injured usually has a decreased LOC, at least temporarily. As a result, the patient cannot chew or swallow and must receive nutrition and fluids by other methods. If LOC does not improve, long-term nutritional support by enteral feeding is used. A small-lumen nasogastric or nasoduodenal tube or a percutaneous endoscopic gastrostomy (PEG) tube is inserted for continuous or intermittent feeding. Small-bore tubes decrease the risk for aspiration in a patient who is at high risk. For care of the patient receiving enteral feeding, see Chapter 63.

With the use of either type of tube, be sure that unlicensed assistive personnel (UAP) weigh the patient daily. Collaborate with the dietitian to determine whether caloric needs are being met. Monitor serum prealbumin levels to assess adequacy of protein intake. Assess the patient daily for signs of dehydration, such as dry mucous membranes and weight loss.

For the patient who can take food and fluids by mouth, ensure that mealtime is a pleasant experience. Position the patient to maximize swallowing ability. The speech-language pathologist (SLP) identifies strategies to prevent food from accumulating in the cheek of the affected side. In general, patients who have swallowing problems can tolerate or swallow soft or semisoft foods and liquids (mechanical soft or dental diet, junior baby foods, custards, scrambled eggs) better than thin liquids (water, juice, milk). Powdered thickener (e.g., Thick-It) may be added to thicken foods for better consistency. Supplements such as milkshakes and commercial products may be needed to meet the patient's caloric and protein requirements. Collaborate with the dietitian and SLP to create a nutritional plan appropriate for the patient with dysphagia.

Managing Sensory, Cognitive, and Behavioral Changes. If a large lesion of the parietal lobe is present, the patient may

experience a loss of sensation for pain, temperature, touch, and proprioception (position sense), which prevents an appropriate response to environmental stimuli. A hazard-free environment is necessary to prevent injury (e.g., from burns if the patient's coffee is too hot). In collaboration with the rehabilitation therapist, integrate a sensory stimulation program into the comatose or stuporous patient's routine care activities. Sensory stimulation is done to facilitate a meaningful response to the environment. Present visual, auditory, or tactile stimuli one at a time, and explain the purpose and the type of stimulus presented. For example, show a picture of the patient's mother and say, "This is a picture of your mother." The picture is shown several times, and the same words are used to describe the picture. If auditory tapes or DVDs are used, they should be no longer than 10 to 15 minutes. If the stimulus is presented for a longer period, it simply becomes "white" noise, or meaningless background noise.

Patients with a milder injury may be disoriented and have a short-term memory loss. Always introduce yourself before any interaction. Keep explanations of procedures and activities short and simple, and give them immediately before and throughout patient care. To the extent possible, maintain a sleep-wake cycle with scheduled rest periods. Orient the patient to time (day, month, and year) and place, and explain the reason for the hospitalization. Reassure the patient that he or she is safe. Ask the family to bring in familiar objects, such as pictures. Provide orientation cues within the environment, such as a large clock with numbers or a single-date calendar.

An overwhelming majority of brain injury survivors have cognitive impairments, or thinking problems. Cognitive impairments interfere with the brain-injured patient's ability

to function effectively in school, at work, and in his or her personal life. *Cognitive rehabilitation* is a way of helping brain-injured patients regain function in areas that are essential for a return to independence and a reasonable quality of life. However, these services are not widely available or accessible.

The patient is at risk for seizure activity. Keep the bed in low position with the siderails up. Use alternatives to restraints first, according to hospital policy. For example, covering the patient's IV site may prevent dislodgment. Keeping the patient's hands busy with activity pillows or puzzles accomplishes the same purpose.

Apply hand mittens if these measures are not successful and the patient attempts to pull out the IV line, nasogastric tube, or endotracheal tube. Restraining any extremity increases agitation and fear. Be sure to follow the agency's policy for caring for patients in restraints, if needed. Release hand mitten restraints every 2 hours, perform passive range of motion, and wash the patient's hands. If the patient is able, assist with toileting and provide water.

Orient the patient to the surroundings as needed, and provide a quiet environment. Closely monitor the patient's response to television programs or the radio. Often he or she cannot distinguish the programs from what is happening within his or her own environment.

Surgical Management

The physician may elect to insert an intracranial pressure (ICP) monitoring device, using minimally invasive surgery (MIS), to evaluate the patient's ICP more closely (Table 47-5). All devices are inserted through a *burr hole* (also known as a *keyhole craniotomy*). Each device is connected to an electronic transducer that converts ICP to electronic impulses and

TABLE 47-5 ADVANTAGES AND DISADVANTAGES OF INTRACRANIAL PRESSURE MONITORING DEVICES

MONITORING DEVICE	ADVANTAGES	DISADVANTAGES
Intraventricular catheter (IVC)	- Allows accurate measurement of intracranial pressure (ICP) - Allows drainage or sampling of cerebrospinal fluid (CSF) - Allows instillation of contrast media - Provides reliable evaluation of cerebral compliance	- Provides additional site for potential infection - Most invasive method for monitoring ICP - Must be balanced and recalibrated frequently - Catheter can become occluded by blood or tissue - Insertion can be difficult with small or collapsed ventricles - CSF leakage can occur around insertion site
Subarachnoid bolt or screw	- Lower infection rates than with IVC - Quickly and easily placed - Can be used with small or collapsed ventricles - Does not penetrate brain parenchyma	- Tendency for dampened waveform - Less accurate at high ICP - May become occluded by blood or tissue - Must be balanced and recalibrated frequently (i.e., every 4 hr and whenever patient is repositioned) - Baseline drift - Does not provide for CSF sampling
Subdural/epidural catheter or sensor	- Least invasive - Decreased risk for infection - Easily and quickly placed	- Increasing baseline drift over time; therefore accuracy and reliability are questionable - Does not provide for CSF sampling or drainage
Fiberoptic transducer-tipped catheter	- Can be placed in subdural or subarachnoid space, in ventricle, or into brain tissue - Easily transported - Requires calibrating only once (during insertion) - Baseline drift to 1 mm Hg/day - Decreased risk for infection - Less waveform artifact - No need to adjust transducer to patient's position - Easy to insert	- Does not provide for CSF sampling or drainage - Cannot be recalibrated after placement - Probe needs periodic replacement - Fragile fiberoptic cable easily damaged and broken

provides information that can be viewed using a monitor at the patient's bedside. The monitor can record the pressure waves and provide a digital readout of the pressure. *Be sure to provide ongoing head-to-toe assessments even though the patient's ICP is being invasively monitored!*

In extreme cases in which the patient's ICP cannot be controlled, the physician may elect to perform a **craniotomy** (incision into the cranium) to remove ischemic tissue or the tips of the temporal lobes. The removal of nonvital brain tissue allows expansion of brain tissue without further increasing ICP. A craniotomy may also be performed to remove epidural or subdural hematomas. Care of the patient with a craniotomy is discussed on p. 1034 under Postoperative Care in the Brain Tumors section.

Community-Based Care

The patient with a *minor* or *moderate* head injury recovers at home after discharge from the emergency department (ED) or hospital (**Chart 47-9**). The patient with a *major* head injury requires long-term case management and ongoing rehabilitation after hospitalization. A number of specialized head injury rehabilitation facilities are available in the United States and Canada. Communicate the patient's plan of care, including drug therapy (reconciliation), to the nurse in the rehabilitation facility to ensure continuity of care (per The Joint Commission's National Patient Safety Goals).

Home Care Management

The major desired outcome for rehabilitation after head injury is to maximize the patient's ability to return to his or her highest level of functioning. Activities such as

occupational therapy (OT), physical therapy (PT), and speech-language therapy may continue in the home after discharge from the rehabilitation facility. Adaptation of the home environment to accommodate the patient safely may be needed. For example, smoke and fire alarms must function properly because the patient with a head injury often loses the sense of smell. This information can be obtained from the admission data or by a home visit. Home adaptations and referrals to outside agencies are completed before discharge.

Teaching for Self-Management

Collaborate with the case manager (CM) to provide the patient and family with both written and verbal instructions for discharge. The teaching plan includes a review of seizure precautions and strategies to adapt to sensory dysfunction. Discuss issues related to personality or behavior problems that may arise and how to cope with them. Explain the purpose, dosage, schedule, and route of administration of drug therapy. Teach the family to encourage the patient to participate in activities as tolerated. Demonstrations and return demonstrations of care activities help family members become more skillful. Stress the importance of regular follow-up visits with therapists and other health care providers.

Patients with personality and behavior problems respond best to a structured and consistent environment. Instruct the family to develop a home routine that provides structure, repetition, and consistency. Remind the family about the importance of reinforcing positive behaviors rather than negative behaviors.

CHART 47-9 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Minor Head Injury

- If the person is sleeping, wake him or her every 3 to 4 hours for the first 2 days, asking his or her name, where he or she is, and the name of the caregiver.
- Expect the person to report headache, nausea, or dizziness for at least 24 hours. If these symptoms are severe or do not improve, contact the physician immediately or take the person back to the emergency department.
- For a headache, give acetaminophen (Tylenol) every 4 hours as needed.
- Avoid giving the person sedatives, sleeping pills, or alcoholic beverages for at least 24 hours unless the physician instructs otherwise.
- Do not allow the person to engage in strenuous activity for at least 48 hours.
- Do not allow nose blowing or ear cleaning for 48 hours.
- If any of these symptoms occur, take the person back to the emergency department immediately:
 - Blurred vision
 - Drainage from the ear or nose
 - Weakness
 - Slurred speech
 - Progressive sleepiness
 - Vomiting
 - Worsening headache
 - Unequal pupil size
- Keep follow-up appointments with the health care provider.

! NURSING SAFETY PRIORITY

Action Alert

Teach the patient who has sustained a *minor* head injury (e.g., a concussion) that **post-concussion syndrome** may occur. This syndrome is a group of clinical manifestations including, but not limited to:

- Personality changes
- Irritability
- Headaches
- Dizziness
- Restlessness
- Nervousness
- Insomnia
- Memory loss
- Depression

A few patients have post-concussion syndrome for weeks, months, or even years to the extent that it interferes with daily activities such as employment. The prolonged pattern is classified as post-trauma syndrome. The exact cause is not known.

Most patients with *moderate to severe* TBI are discharged with varied physical and cognitive disabilities. Changes in personality and behavior are very common. The family must learn to cope with the patient's increased fatigue, irritability, temper outbursts, depression, and memory problems. These patients often require constant supervision at home, and families may feel socially isolated. Teach the family about the importance of regular respite care, either in a structured day-care respite program or through relief provided by a friend or neighbor. Family members, particularly the primary caregiver, may become depressed and have feelings of loneliness.

In addition, they may feel angry with the patient because of the additional responsibilities (financial and emotional) that his or her care has placed on them. To help the family cope with these problems, suggest that they join and actively participate in a local head injury support group.

Health Care Resources

Collaborate with the CM to refer families and patients to local chapters of the Brain Injury Association of America (BIAA) (www.biausa.org) and the National Brain Injury Foundation (NBIF) (www.nbif.org) for information and support. The BIAA has a number of helpful publications on preventing and living with TBI. Other resources include religious, spiritual, and cultural leaders.

BRAIN TUMORS

Brain tumors can arise anywhere within the brain structures and are named according to the cell or tissue where they are located; however, cerebral tumors are the most common. *Primary* tumors originate within the central nervous system (CNS) and rarely **metastasize** (spread) outside this area. *Secondary* brain tumors result from metastasis from other areas of the body, such as the lungs, breast, kidney, and GI tract.

Pathophysiology

Complications of Cerebral Tumors

Regardless of location, the tumor expands and invades, infiltrates, compresses, and displaces normal brain tissue. This leads to one or more of these problems:

- Cerebral edema/brain tissue inflammation
- Increased intracranial pressure (ICP)
- Neurologic deficits
- Hydrocephalus
- Pituitary dysfunction

Cerebral edema (vasogenic edema) results from changes in capillary endothelial tissue permeability that allow plasma to seep into the extracellular spaces. This leads to *increased ICP* and, depending on the location of the tumor, brain herniation syndromes. A variety of *neurologic deficits* result from edema, infiltration, distortion, and compression of surrounding brain tissue. The cerebral blood vessels may become compressed because of edema and increased ICP. This compression leads to ischemia (decreased blood flow) of the area supplied by the vessel. In addition, the tumor may enter the walls of the vessel, causing it to rupture and hemorrhage into the tumor bed or other brain tissue. Some patients who have brain tumors have seizure activity from interference with the brain's normal electrical activity.

Increased ICP may also result from *hydrocephalus* (increased cerebrospinal fluid [CSF]) related to obstruction of the flow of CSF or displacement of the lateral ventricles by the expanding lesion. Typically, a tumor obstructs the aqueduct of Sylvius or one of the ventricles or pushes into the subarachnoid space.

Pituitary dysfunction may occur as the tumor compresses the pituitary gland and causes the syndrome of inappropriate antidiuretic hormone (SIADH) or diabetes insipidus (DI). These disorders result in severe fluid and electrolyte imbalances and can be life threatening. (See [Chapter 65](#) for a complete description.)

TABLE 47-6 CLASSIFICATION OF BRAIN TUMORS

Benign	Malignant
• Acoustic neuroma • Meningioma • Pituitary adenoma • Astrocytoma • Grade 1 (may undergo changes and become malignant) • Chondroma • Craniopharyngioma • Hemangioblastoma	• Astrocytoma • Grade 2 • Grade 3 • Grade 4 (also known as <i>glioblastoma multiforme</i>) • Oligodendroglioma • Ependymoma • Medulloblastoma • Chondrosarcoma • Glioma • Lymphoma

Classification of Tumors

Brain tumors are usually classified as benign, malignant (cancerous), or metastatic ([Table 47-6](#)). They may or may not be treated, depending on their location. Benign (non-cancerous) tumors are generally associated with a favorable outcome. Malignant or metastatic tumors require more aggressive intervention including surgery, radiation, and/or chemotherapy.

A second classification system is based on location. **Supratentorial** tumors are located within the cerebral hemispheres. Located beneath the tentorium (fold of dura mater) is the **infratentorial** area—the area of the brainstem structures and cerebellum.

A third classification system depends on the cellular or anatomic origins of the tumor. The nervous system is composed of two types of cells: (1) neurons, which are responsible for nerve impulse conduction; and (2) neuroglial cells, which provide support, nourishment, and protection for neurons. Four specific types of neuroglial cells are astrocytes, oligodendroglia, ependymal cells, and microglia. When classifying gliomas according to this system, tumors are named by their cell type. For example, an astrocytoma is a tumor of astrocytes. Gliomas are *malignant* tumors.

Meningiomas, the most common **benign** tumors, arise from the coverings of the brain (the meninges). This tumor is capsular, globular, and well outlined and causes compression and displacement of nearby brain tissue. Although complete removal of the tumor is possible, it tends to recur.

Pituitary tumors that occur in the anterior lobe account for up to one fourth of brain tumors and may cause endocrine dysfunction. The most common type of pituitary tumor is the adenoma. These tumors are *benign* and often occur in young and middle-aged adults. The presenting symptoms include visual disturbances and hypopituitary signs, such as loss of body hair, diabetes insipidus (DI), infertility, visual field defects, and headaches.

Acoustic neuromas arise from the sheath of Schwann cells in the peripheral portion of cranial nerve VIII. They are also referred to as *cerebellar pontine angle (CPA) tumors* to describe their anatomic location. Acoustic neuromas compress brain tissue and tend to surround nearby cranial nerves (VII, V, IX, X), making surgical removal difficult without causing permanent cranial nerve dysfunction. Women are twice as likely as men to have acoustic neuromas. Common symptoms include hearing loss, **tinnitus** (ringing in the ears), and dizziness or vertigo.

Metastatic, or secondary, tumors account for many brain tumors. Cancer cells from the lung, breast, colon, pancreas, and kidney can travel to the brain via the blood and the lymphatic system. Multiple metastatic lesions are fairly common.

Etiology and Genetic Risk

The exact cause of brain tumors is unknown. Several areas under investigation include genetic mutations and a variety of environmental factors. The use of cellular phones has been investigated as a cause of brain tumors, but findings are not confirmed.

Incidence/Prevalence

Brain tumors account for a small percentage of all cancer deaths. Primary brain tumors are relatively uncommon; many more patients have metastatic lesions (Cahill & Armstrong, 2011). Malignant brain tumors are seen primarily in patients 40 to 70 years of age, and the survival rate is low compared with that of other cancers.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

When possible, obtain a history from both the patient and the family, including current signs and symptoms. A complete neurologic assessment is needed to establish baseline data and to determine the nature and extent of neurologic deficits.

The clinical manifestations of brain tumors vary with the site of the tumor (Chart 47-10). In general, assess for these symptoms of a brain tumor, which include:

- Headaches that are usually more severe on awakening in the morning
- Nausea and vomiting
- Visual symptoms
- Seizures

CHART 47-10 KEY FEATURES

Common Brain Tumors

Cerebral Tumors

- Headache (most common feature)
- Vomiting unrelated to food intake
- Changes in visual acuity and visual fields; diplopia (visual changes caused by papilledema)
- Hemiparesis or hemiplegia
- Hypokinesia (decreased motor ability)
- Hyperesthesia, paresthesia, decreased tactile discrimination
- Seizures
- Aphasia
- Changes in personality or behavior

Brainstem Tumors

- Hearing loss (acoustic neuroma)
- Facial pain and weakness
- Dysphagia, decreased gag reflex
- Nystagmus
- Hoarseness
- Ataxia and dysarthria (cerebellar tumors)

- Changes in mentation or personality
- **Papilledema** (swelling of the optic disc)

Neurologic deficits result from the destruction, distortion, or compression of brain tissue. *Supratentorial (cerebral)* tumors usually result in paralysis, seizures, memory loss, cognitive impairment, language impairment, or vision problems. *Infratentorial* tumors produce ataxia, autonomic nervous system dysfunction, vomiting, drooling, hearing loss, and vision impairment. As the tumor grows, ICP increases and the symptoms become progressively more severe.

Diagnosis is based on the history, neurologic assessment, clinical examination, and results of neurodiagnostic testing. Noninvasive diagnostic studies such as CT, MRI, and skull films are conducted first. These tests identify the size, location, and extent of the tumor. The MRI may be used for initial diagnostic evaluation and is a more sensitive diagnostic study, whereas the CT is often used for follow-up during the course of illness.

Cerebral angiography is usually not indicated to diagnose a brain tumor but may be used to provide additional information about blood supply to the tumor. Electroencephalography (EEG), lumbar puncture (LP), brain scan, and positron emission tomography (PET) may be indicated to provide further information about the size, location, and characteristics of the tumor. *To prevent brain herniation, LP should not be performed if the patient is exhibiting signs of ICP elevation.* Laboratory tests may also be requested to evaluate endocrine function, renal status, and electrolyte balance.

INTERVENTIONS

Interventions depend on the type, size, and location of the tumor. For example, a small benign tumor may be periodically monitored through CT and MRI scanning to assess its growth. Malignant tumors may be managed by chemotherapy, radiation, and/or surgery.

Nonsurgical Management

The desired outcomes of treatment of brain tumors are to decrease tumor size, improve quality of life, and improve survival time. The type of treatment selected depends on the tumor size and location, patient symptoms and general condition, and whether the tumor has occurred again. In addition to traditional interventions, a number of experimental treatment modalities are being investigated. These include blood-brain barrier disruption, recombinant DNA, monoclonal antibodies, new chemotherapeutic drugs, and immunotherapy. For example, an antitenascin radioactive monoclonal antibody treatment (81C6) that is directly injected into the cavity where the tumor was removed is being investigated. The antibodies deliver radiation directly into the brain but are less potent than traditional radiation.

Traditional *radiation therapy* may be used alone, after surgery, or in combination with chemotherapy and surgery. Chapter 24 discusses radiation treatment for patients with cancer.

Drug Therapy. The health care provider may prescribe a variety of drugs to treat the tumor, manage the patient's symptoms, and prevent complications. *Chemotherapy* may be given alone, in combination with radiation and surgery, and with tumor progression. Although these drugs may control tumor growth or decrease tumor burden, the benefit does not

last. Chemotherapy usually involves more than one agent that may be given orally, IV, intra-arterially, and/or intrathecally through an Ommaya reservoir placed in a cranial ventricle. In electrochemotherapy, electric voltage carries agents into the tumor. When given systemically, the drug must be lipid-soluble to cross the blood-brain barrier.

Commonly used oral drugs are CCNU (lomustine), temozolomide (Temodar), procarbazine (Matulane), and methotrexate (MTX). Vincristine (Oncovin) may be given IV in combination with other drugs. Monitor for side effects of these drugs, which are similar to those of any chemotherapeutic drug. Chapter 24 describes general nursing implications for care of a patient receiving chemotherapy.

Direct drug delivery to the tumor is an emerging practice. Disk-shaped drug (Gliadel) wafers may be placed directly into the cavity created during surgical tumor removal (interstitial chemotherapy). The major drug in the wafer is BCNU (carmustine). This therapy is usually used for newly diagnosed high-grade malignant gliomas, but recurrent tumors may also be treated with this method. Other drugs used are molecularly targeted. Examples include erlotinib (Tarceva), gefitinib (Iressa), and bevacizumab (Avastin).

Analgesics, such as codeine and acetaminophen (Tylenol, Ace-Tabs), are given for headache. Dexamethasone (Decadron) is usually given to control cerebral edema. Glucocorticoids may be used for the treatment of edema resulting from brain tumors. Phenytoin (Dilantin) or other antiepileptic drugs may be given to prevent or treat seizure activity. Proton pump inhibitors such as IV or oral pantoprazole (Protonix) are given to decrease gastric acid secretion and prevent the development of stress ulcers.

Stereotactic Radiosurgery. Stereotactic radiosurgery (SRS) is an alternative to traditional surgery. Several techniques are used, including the modified linear accelerator (LINAC) using accelerated x-rays, a particle accelerator using beams of protons (cyclotron), and isotope seeds implanted in the tumor (brachytherapy). The gamma knife and CyberKnife are the newest treatments.

The gamma knife is a SRS procedure that uses a single high dose of ionized radiation to focus multiple beams of gamma radiation produced by the radioisotope *cobalt-60* to destroy intracranial lesions selectively without damaging surrounding healthy tissue (Fig. 47-10). Combining neurodiagnostic imaging tools—including MRI, CT, magnetic resonance angiography (MRA), and angiography—with the gamma knife allows for precise localization of deep-seated or anatomically difficult lesions. Treatment usually takes less than an hour, and patients require only overnight hospitalization. Advantages of this technique include its:

- Noninvasive nature
- Lower risk when compared with traditional craniotomy
- Surgical precision
- Decreased cost
- Decreased morbidity
- Decreased length of hospital stay
- Rapid recovery time

A disadvantage is that the device requires an uncomfortable rigid head frame. In another system called the *CyberKnife*, no frame is needed.

Both procedures are used primarily for brain tumors or arteriovenous malformations (AVMs) that are in a difficult

FIG. 47-10 A gamma knife treatment. The treatment beams are widely dispersed over the surface of the head to prevent damage to healthy brain tissue. The beams are intense only at the point of target.

location and therefore not removable by craniotomy. These procedures may also be used with patients who refuse conventional surgery, for patients whose age and physical condition do not allow general anesthesia, as an adjunct to radiation therapy, and for recurrent or residual AVM or tumors after embolization or craniotomy.

Surgical Management

Brain biopsy may be done to determine the specific pathology of the tumor. Then, a **craniotomy** (incision into the cranium) may be performed to improve symptoms related to the lesion or to decrease pressure from the tumor. The challenge for the neurosurgeon is to remove the tumor as completely as possible without damaging normal tissue. Complete removal is possible with some benign tumors, which results in a “surgical cure.” Postoperatively, the patient is admitted to the critical care unit.

Preoperative Care. The patient having a craniotomy is typically very anxious about having his or her head opened and the brain exposed. Concerns are centered on the possibility of increased neurologic deficits after the surgery and the patient’s self-image when part or all of the head is shaved. Provide reassurance that the surgeon will spare vital parts of the brain while removing or decreasing the size of the tumor. Teach the patient and family about what to expect immediately after surgery and throughout the recovery period. Some patients require short-term or long-term rehabilitation.

Check that the patient has not had alcohol, tobacco, anti-coagulants, or NSAIDs for at least 5 days before surgery. Some neurosurgeons require a week or longer. Be sure that the patient has been NPO status for at least 8 hours. Other preoperative care is similar to that for any patient having surgery, as described in Chapter 16.

Operative Procedures. Surgery is performed under local or general anesthesia or sedation. Small tumors that are easily located may be removed by *minimally invasive surgery (MIS)*. For example, the trans-nasal approach using endoscopy can be performed for pituitary tumors. The patient has a short hospital stay and few complications after surgery. Stereotactic surgery using a rigid head frame can be done for tumors that are easily reached. This procedure requires only burr holes

and local anesthesia because the brain has no sensory neurons for pain. Laser surgery can also be done.

For a *craniotomy*, the surgeon makes an incision along or behind the hairline after placing the patient's head in a skull fixation device. Several burr holes are drilled into the skull, and a saw is used to remove a piece of bone (bone flap) to expose the tumor area. The flap is stored carefully until the end of the procedure. The tumor is located using imaging technology and removed or debulked (decreased in size). After the tumor removal, the bone flap is replaced and held by small screws or bolts. A drain or monitoring device may be inserted. The surgeon creates a soft dressing "cap" over the top of the head to keep the surgical area clean.

Postoperative Care. The focus of postoperative care is to monitor the patient to detect changes in status and to prevent or minimize complications, especially increased intracranial pressure (ICP).

! NURSING SAFETY PRIORITY

Action Alert

Assess neurologic and vital signs every 15 to 30 minutes for the first 4 to 6 hours after a craniotomy and then every hour. If the patient is stable for 24 hours, the frequency of these checks may be decreased to every 2 to 4 hours, depending on the agency's policy or the patient's condition. Report immediately and document new neurologic deficits, including a decreased level of consciousness (LOC), motor weakness or paralysis, aphasia (speech and/or language problems), visual changes, and personality changes!

Periorbital (around the eye) edema and ecchymosis of one or both eyes are not unusual and are treated with cold compresses to decrease swelling. Irrigate the affected eye with warm saline solution or artificial tears to improve patient comfort. If the patient is still recovering from anesthesia, has a decreased LOC, or may not be able to protect the airway, he or she may remain intubated and have controlled mechanical ventilation.

Providing Nursing Care. The patient in the critical care unit has routine cardiac monitoring because dysrhythmias may occur as a result of fluid and electrolyte imbalance. Ensure strict recording of the patient's intake and output and possible fluid restriction to 1500 mL daily if clinically indicated (e.g., pituitary complications). Teach unlicensed assistive personnel (UAP) to perform gentle range-of-motion exercises to all extremities at least every 2 to 3 hours. Delegate and supervise turning and deep breathing every 2 hours. To prevent the development of deep vein thrombosis, maintain sequential compression stockings or pneumatic compression boots until the patient ambulates.

For patients who have undergone *supratentorial* surgery, elevate the head of the bed 30 degrees or as tolerated to promote venous drainage from the head. *Position the patient to avoid extreme hip or neck flexion and maintain the head in a midline, neutral position to prevent increased ICP.* Turn the patient side to side or supine to prevent pressure ulcers and prevent pneumonia. If a large tumor has been removed, place the patient on the nonoperative side to prevent displacement of the cranial contents by gravity.

Keep the patient with an *infratentorial* (brainstem) craniotomy flat and positioned on either side for 24 to 48 hours. This position prevents pressure on the neck-area incision site.

It also prevents pressure on the internal tumor excision site from higher cerebral structures. Make sure that the patient remains NPO status for 24 hours, because edema around the medulla and lower cranial nerves may cause vomiting and aspiration.

Check the head dressing every 1 to 2 hours for signs of drainage. Mark the area of drainage once during each shift for baseline comparison, although this practice varies by health care agency. A small or moderate amount of drainage is expected. Some patients may have a Hemovac, Jackson-Pratt, or other surgical drain in place for 24 hours after surgery. Measure the drainage every 8 hours, and record the amount and color. A typical amount of drainage is 30 to 50 mL every 8 hours. Follow the manufacturer's and neurosurgeon's instructions to maintain suction within the drain.

! NURSING SAFETY PRIORITY

Critical Rescue

After craniotomy, monitor the patient's dressing for excessive amounts of drainage. Report a saturated head dressing or drainage greater than 50 mL/8 hr immediately to the surgeon! Observe for manifestations of hypovolemic shock, and position the patient flat to maintain blood pressure if needed.

The usual laboratory studies monitored postoperatively include complete blood count (CBC), serum electrolyte levels and osmolarity, coagulation studies, and arterial blood gas (ABG) measurements. The patient's hematocrit and hemoglobin concentration may be abnormally low from blood loss during surgery or elevated if the blood was replaced. Hyponatremia (low serum sodium) may occur as a result of fluid volume overload, syndrome of inappropriate antidiuretic hormone (SIADH), or steroid administration.

Hypokalemia (low serum potassium) may cause cardiac irritability. Weakness, a change in LOC, and confusion are symptoms of hyponatremia and hypokalemia. Hypernatremia may be caused by meningitis, dehydration, or diabetes insipidus (DI). It is manifested by muscle weakness, restlessness, extreme thirst, and dry mouth. Additional signs of dehydration such as decreased urinary output, thickened lung secretions, and hypotension may be present. *Untreated hypernatremia can lead to seizure activity. DI should be considered if the patient voids large amounts of very dilute urine with an increasing serum osmolarity and electrolyte concentration.*

Often the patient is mechanically ventilated and hyperventilated for the first 24 to 48 hours after surgery to help prevent increased ICP and improve cerebral oxygen levels. The desired outcome of controlled ventilation is to keep the partial pressure of arterial carbon dioxide (Paco₂) at about 35 mm Hg, with normal arterial oxygen levels. This intervention is designed to avoid cerebral vasodilation from increased carbon dioxide with the resulting rise in ICP. If the patient is awake or attempting to breathe at a rate other than that set on the ventilator, drugs such as fentanyl citrate or midazolam (Versed) are given to treat pain and anxiety, as well as to promote rest and comfort. Suction the patient as needed. *Remember to hyperoxygenate the patient carefully before, during, and after suctioning!*

Drugs routinely given postoperatively include antiepileptic drugs, histamine blockers, proton pump inhibitors, and corticosteroids, such as dexamethasone (Decadron). Give

analgesics such as codeine for pain, and give acetaminophen for fever or mild pain. Some surgeons may elect to administer prophylactic antibiotics to prevent infection.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client returns from the postanesthesia care unit (PACU) after a craniotomy for removal of a right frontal lobe tumor. How will the nurse position the client after surgery?

- A. Flex the client's knees to decrease intra-abdominal pressure.
- B. Keep the client on the right side to prevent surgical site bleeding.
- C. Elevate the client's head to at least 30 degrees to promote venous drainage.
- D. Log roll the client, and keep the head elevated at no more than 15 degrees.

Preventing and Managing Postoperative Complications. Postoperative complications are listed in Table 47-7. The major complication of supratentorial surgery is increased ICP from cerebral edema, hemorrhage, or obstruction of the normal flow of cerebrospinal fluid (CSF).

Symptoms of *increased ICP* include severe headache, deteriorating LOC, restlessness, irritability, and dilated or pinpoint pupils that are slow to react or nonreactive to light. Treatment of increased ICP is the same as that described on p. 1027 under Interventions in the Traumatic Brain Injury section.

Subdural and epidural *hematomas and intracranial hemorrhage* are manifested by severe headache, a rapid decrease in LOC, progressive neurologic deficits, and herniation syndromes (brain tissue shifting, often downward). Bleeding into the posterior fossa may lead to sudden cardiovascular and respiratory arrest. Treatment of a hematoma requires surgical removal. An intracranial hemorrhage is treated with aggressive medical management (e.g., osmotic diuretics, ICP monitoring).

Hydrocephalus (increased CSF in the brain) is caused by obstruction of the normal CSF pathway from edema, an expanding lesion such as a hematoma, or blood in the subarachnoid space. Rapidly progressive hydrocephalus produces the classic symptoms of increased ICP. Slowly progressive hydrocephalus is manifested by headache, decreased LOC, irritability, blurred vision, and urinary incontinence. An intraventricular catheter (**ventriculostomy**) may be placed as

an emergency procedure to drain CSF for rapidly deteriorating neurologic function. If long-term treatment is required for chronic hydrocephalus, a surgical shunt is inserted to drain CSF to another area of the body. A major complication of the shunting procedure is a subdural hematoma from the tearing of bridging veins. An external lumbar drain may also be used temporarily. Additional information about shunts may be found in neuroscience nursing textbooks.

Respiratory complications include atelectasis, pneumonia, and neurogenic pulmonary edema. Prevent atelectasis and pneumonia by turning the patient frequently and encouraging him or her to take frequent deep breaths to expand the lungs each hour. Humidified air and incentive spirometry are also useful techniques. Other treatment modalities include endotracheal or oral tracheal suctioning and chest physiotherapy. However, these measures may cause an increase in ICP.

Although not common, *neurogenic pulmonary edema* is a life-threatening complication of traumatic brain injury (TBI), brain tumors, and brain surgery. Its symptoms are the same as those of acute pulmonary edema, but there are no associated cardiac problems. In spite of aggressive treatment, most patients with neurogenic pulmonary edema do not survive.

Wound infections occur more often in older and debilitated patients and in patients with a history of diabetes, long-term steroid use, obesity, and previous infections. The patient may contribute to the problem by rubbing or scratching the wound. If infection is present, the wound appears reddened and puffy. It may begin to separate, is sensitive to touch, and feels warm. The patient may or may not be febrile. Treatment is based on the degree and extent of the infection. A localized infection may be treated by cleaning it with an antiseptic and applying local antibiotics. For more severe infections, systemic antibiotic administration is needed. If the underlying bone is involved, it may need to be removed.

Meningitis is an inflammation of the meninges and may occur as a result of surgery or wound infection, a cerebrospinal fluid (CSF) leak, or contamination during surgery. (See the discussion of meningitis in Chapter 44 for a more complete explanation of this complication.)

Complications related to *fluid and electrolyte imbalance* include DI, SIADH, and cerebral salt wasting (CSW). DI is seen most often after supratentorial surgery, especially procedures involving the pituitary gland or hypothalamus. Failure of the posterior pituitary gland to release antidiuretic hormone (ADH) leads to failure of the renal tubules to reabsorb water. The patient's urine output increases dramatically (it may be up to 10 L/day), and the urine specific gravity drops to below 1.005. Urine osmolality decreases, whereas serum osmolality increases. The patient may become dehydrated, and hypovolemic shock may develop rapidly if this condition is left untreated. Fluid therapy to replace urinary losses and prevent dehydration may be accomplished by having the patient increase oral intake or use IV fluids. Hormonal replacement may also be necessary, especially if fluid loss is greater than 6 L/24 hr. Aqueous vasopressin is short-acting, lasting only 6 to 8 hours. Desmopressin acetate (DDAVP) may be administered for long-term replacement therapy.

Syndrome of inappropriate antidiuretic hormone (SIADH) occurs when the posterior pituitary gland releases too much ADH, causing water retention. The urine output decreases dramatically, with a urine output of less than 20 mL/hr.

TABLE 47-7 POSTOPERATIVE COMPLICATIONS OF CRANIOTOMY

- Increased intracranial pressure (ICP) - Hematomas - Subdural hematoma - Epidural hematoma - Subarachnoid hemorrhage - Hypovolemic shock - Hydrocephalus - Respiratory complications - Atelectasis - Hypoxia - Pneumonia - Neurogenic pulmonary edema	- Wound infection - Meningitis - Fluid and electrolyte imbalances - Dehydration - Hyponatremia - Hypernatremia - Seizures - Cerebrospinal fluid (CSF) leak - Cerebral edema
---	---

Sodium concentration in the urine is normal or elevated, whereas the serum sodium level falls. Other indications of SIADH are loss of thirst, weight gain, irritability, muscle weakness, and decreased LOC. SIADH is treated by fluid restriction, which is usually sufficient to correct the hyponatremia. Slow, controlled IV infusion of 3% hypertonic sodium may be needed for severe hyponatremia (<118 mEq/L).

Cerebral salt wasting (CSW) is thought to result from the influence of atrial natriuretic factor (ANF). ANF cells are located in the hypothalamus and the right atrium and regulate fluid volume. CSW is believed to be the primary cause of hyponatremia in the neurosurgical population. It is characterized by hyponatremia, decreased serum osmolarity, and decreased blood volume. Serum vasopressin and ANF levels can differentiate CSW and SIADH. CSW is treated with the replacement of sodium and isotonic fluid volume.

Patients with complications related to fluid and electrolyte imbalance undergo strict measurement of their intake and output. Be sure that an accurate weight measurement is taken every day at the same time with the same scale. Carefully assess for indications of fluid overload or dehydration during treatment. Serum electrolyte levels and osmolarity are measured daily (or more often if clinically indicated).

Community-Based Care

The patient with a brain tumor is managed at home if possible. Maintaining a reasonable quality of life is an important outcome for recovery and rehabilitation. Unless the patient has a significant degree of disability, no special preparation for home care is needed. Patients with hemiparesis need assistance to ensure that their home is accessible according to their method of mobility (e.g., cane, walker, wheelchair). The environment should be made safe to prevent falls. For example, teach caregivers to remove scatter rugs and to place grab bars in the bathroom.

Information about the selection of rehabilitation or chronic care facility, if needed, can be obtained from the case manager (CM) or discharge planner. The selected facility should have experience in providing care for neurologically impaired patients. A psychologist should be available to provide input in the evaluation of the cognitive disabilities that the patient may have.

It is very important that the patient and family fully understand the importance of any recommended follow-up health care appointments. The discharge summary should state the name of the person who has been given the follow-up information.

Health teaching includes drug therapy and who to call if adverse drug events occur. Remind the patient to avoid taking any over-the-counter drugs unless approved by the health care provider.

Teach the patient to maintain a program of regular physical exercise within the limits of any disabilities. Referral to the dietitian may be needed to ensure adequate caloric intake for the patient receiving radiation or chemotherapy.

Seizures are a potential complication that can occur at any time for as long as 1 year or more after surgery. Provide the patient and the family with information about seizure precautions and what to do if a seizure occurs.

Refer the patient and the family or significant others to the American Brain Tumor Association (www.abta.org) or the National Brain Tumor Foundation (www.braintumor.org). The American Cancer Society (www.cancer.org) is also an

appropriate community resource for patients with malignant tumors. Home care agencies are available to provide both the physical and rehabilitative care that the patient may need at home. Hospice services and palliative care may be needed if he or she is terminally ill. (See [Chapter 9](#) for additional information.) Brain tumor support groups may also be a valuable asset to the patient and family.

BRAIN ABSCESS

A **brain abscess** is a purulent infection of the brain in which pus forms in the extradural, subdural, or intracerebral area of the brain. The causative organisms are usually bacteria that invade the brain directly or indirectly. Cerebral abscesses may be a complication of meningitis.

Pathophysiology

In general, organisms from the ear, sinus, or mastoid area enter the brain by traveling along the wall of the cerebral veins, and therefore they may spread to any area of the brain. At times, the organisms (especially those from the ear) destroy the bone, form a tract, and enter the brain directly. Septic emboli (dislodged clots) from the heart, the lungs, or a dental or peritonsillar abscess may break off and enter the systemic circulation. These organisms may become lodged in a cerebral vessel and produce a localized infection. Penetrating trauma, open head injuries, and neurosurgical procedures provide a potential means for the direct entry of an organism into the brain.

The organisms cause a local infection, and acute inflammation surrounds the involved area. Within a few days, necrosis of the tissue takes place, pus forms, and the tissue liquefies. This process is followed by the development of cerebral edema from localized vascular congestion and tissue swelling in response to inflammation. During the next few weeks, the area becomes encapsulated. The abscess usually occurs deep within the cerebral hemisphere and involves the white matter of the brain. In a few cases, it spreads through the brain tissue to the subarachnoid space and ventricular system.

The organism varies with the source of the abscess. *Streptococci* are the most common organisms and are often found with other anaerobes such as *Bacteroides*. *Enterobacteriaceae* such as *Escherichia coli* and *Proteus* organisms may also be combined with *Streptococcus*. Yeast and fungi also cause cerebral abscess formation, particularly in patients who are immunosuppressed. *Toxoplasma gondii* is one of the most commonly seen central nervous system (CNS) opportunistic infections in the acquired immune deficiency syndrome (AIDS) population.

Most brain abscesses occur in the frontal and temporal lobes. A few affected patients have more than one abscess. Mortality rates vary up to more than one half of patients with abscesses. Those that occur in immunosuppressed patients are associated with a higher mortality rate.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

The clinical manifestations of a brain abscess begin slowly and are similar to some of the manifestations of meningitis. The patient may have headache, fever, and neurologic deficits

or nonspecific signs and symptoms. Perform ongoing neurologic assessments. The patient may be mildly lethargic or somewhat confused. The pupillary response to light is normal in the early stages. As increased intracranial pressure (ICP) progresses, the pupils may become sluggish, unequal, dilated, and nonresponsive to light. The patient's level of consciousness (LOC) declines to a state in which he or she loses the ability to interact with the environment. Airway and respiratory function may also be altered.

Examination of the patient's visual fields often reveals a **temporal field blindness** (decrease in peripheral vision laterally). If the abscess affects the cerebral hemispheres, nystagmus (involuntary eye movements) may be evident. Motor examination reveals a generalized weakness. More significant motor problems, such as hemiplegia, may be apparent in the presence of a frontal lobe abscess. An ataxic gait is seen with a cerebellar abscess. Sensory impairment varies, although the patient often exhibits no sensory deficits. The patient may have varying degrees of aphasia (impaired communication ability) if he or she has a frontal or temporal lobe abscess. Seizure activity may occur because of irritation of the cortical tissue. Late in the disease process, more severe symptoms of increased ICP occur and include severe headache, decreased LOC (possibly coma), a widened pulse pressure, bradycardia, and irregular respirations. The patient with AIDS often presents with systemic infection, CNS involvement, and lymphoma.

Some patients may have atypical presentations, including older adults (age-related compromise in immune function), those receiving steroid therapy or immune-modulating drugs, and patients with later stages of human immune deficiency virus (HIV) infection (immune system compromise). In the earlier stages, the inflammatory response is responsible for much of the clinical presentation, particularly if cerebral abscess formation results from meningitis. The risk is that the patient may progress to severe abscess formation before the onset of "classic" manifestations.

Diagnostic Assessment

The white blood cell (WBC) count and erythrocyte sedimentation rate (ESR) are usually elevated, indicating the presence of infection. If the abscess is encapsulated, the WBC count may be normal. Obtain specimens for aerobic and, when

possible, anaerobic cultures of the blood, ear, nose, and throat to determine the primary source of infection.

The health care provider requests a CT scan to determine the presence of cerebritis, hydrocephalus, or a midline shift. MRI is also useful in detecting the presence of an abscess early in the course of the disease. An EEG can localize the lesion in most cases and shows high-voltage, slow-wave activity; electro-cerebral silence may be noted in the area of the abscess. Radiography of the sinuses and the mastoid is often indicated. A lumbar puncture may be performed if meningitis is also suspected and the patient does not have ICP elevation. A needle biopsy is performed to identify the cause of the infection.

INTERVENTIONS

Drug therapy is prescribed by the physician to treat the abscess. Typically used antibiotics include penicillin G benzathine (Bicillin) and nafcillin sodium (Nafcil, Unipen). Metronidazole (Flagyl, Novonidazol ) or vancomycin may be used if an anaerobic organism is the causative agent. Antibiotic dosing may be increased to ensure adequate CNS penetration. These agents are particularly useful in the early stages (cerebritis) of abscess formation. A combination of antibiotics is used, particularly if the abscess resulted from septic emboli. Antiepileptic drugs such as phenytoin (Dilantin) may be used to prevent seizures. The drug regimen is strictly followed to maintain therapeutic blood levels. Give analgesics to treat headache.

The physician may surgically drain an encapsulated abscess via a burr hole to reduce the mass effect of the lesion. In certain cases, a craniotomy may be performed to remove the abscess. The decision to perform surgery is based on the patient's general condition, the stage of abscess development, and the site of the abscess. Provide routine preoperative and postoperative care for the patient undergoing a craniotomy, as discussed on p. 1033 under Surgical Management in the Brain Tumors section.

The patient with a brain abscess is discharged to home if few or no neurologic deficits are present. Patients with severe dysfunction are usually transferred to long-term care or a rehabilitation facility. Some patients have permanent neurologic deficits.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing impaired mobility, sensation, and cognition as a result of severe acute neurologic health problems affecting the brain?

- Decreased level of consciousness (LOC)
- Inability to communicate (aphasia)
- Impaired swallowing (dysphagia)
- Weakness or paralysis of one side of the body (hemiparesis or hemiplegia)
- Alteration in gait
- Inability to perform ADLs
- Report of nausea and vomiting
- Report of impaired visual acuity or fields
- Ptosis (eyelid drooping)

- Unilateral body neglect
- Report of decreased peripheral sensation
- Inability to make appropriate judgments; confusion
- Impaired memory
- Report of severe headache

What should you INTERPRET and how should you RESPOND to a patient experiencing impaired mobility, sensation, and cognition as a result of severe neurologic health problems affecting the brain?

Perform and interpret physical assessment, including:

- Assess airway, breathing, and circulation (ABC) status.
- Assess neurologic status, especially LOC and mental state.

NURSING CONCEPT REVIEW—cont'd

- Take vital signs (high blood pressure or widened pulse pressure may indicate increased intracranial pressure [ICP]).
- Assess functional status.
- Assess for swallowing and nutrition status.

Respond by:

- Notifying health care provider or Rapid Response Team if patient is having increased ICP.
- Ensuring an adequate airway.
- Giving oxygen to perfuse the brain.
- Establishing IV access.
- Protecting the patient from injury.

- Collaborating with health care team members as needed to meet patient's needs.
- Assisting with ADLs and mobility as needed.

On what should you REFLECT?

- Think about how you responded.
- Continue to monitor neurologic status.
- Monitor for indications of secondary brain insult as patient is treated.
- Think about what health teaching is needed for the patient and family.
- Provide emotional support for the patient and family.
- Think about what other interventions you could implement in caring for the patient.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- When caring for a patient with a stroke or traumatic brain injury (TBI), assess airway, breathing, and circulation status first and implement interventions to maintain them.
- Monitor patients with critical neurologic health problems for manifestations of increasing intracranial pressure (ICP) as described in [Chart 47-6](#).
- Be aware that the first sign of increased ICP is a *decrease* in level of consciousness (LOC).
- Collaborate with members of the health care team when managing patients with critical neurologic health problems, including the physical and occupational therapists, dietitian, and social worker.
- Coordinate continuity of care with the hospital case manager or discharge planner when discharging or transferring patients to community-based agencies or home.
- Teach patients and families about community organizations, such as the National Stroke Association and the Brain Injury Association of America.

Health Promotion and Maintenance

- Conduct a complete health assessment for patients with a stroke, with an emphasis on neurologic status.
- Teach patients and families about modifiable risk factors for stroke as listed in [Chart 47-2](#).

Psychosocial Integrity

- Assess the emotional reactions of families to a brain cancer diagnosis, and help them cope by providing information and referrals to support systems.
- Teach patients and their families about community resources to help them cope with life changes, especially

community support groups that are provided by state and national organizations.

- Assess patients with strokes for sensory perceptual changes such as unilateral neglect and impaired vision; help patients adapt to these changes, such as turning their head from side to side to see the entire meal tray.

Physiological Integrity

- Recall the differences between a transient ischemic attack and a brain attack (stroke).
- Assess the patient's ability to perform ADLs, including the ability to eat because of swallowing problems.
- Assess for expressive and/or receptive aphasia in patients who have had a stroke.
- Monitor the patient on thrombolytic therapy or anticoagulants for bleeding and abnormal coagulation studies.
- Provide best practices for thrombolytic therapy administration as listed in [Chart 47-5](#).
- Evaluate the collaborative care of the stroke patient by helping him or her achieve the highest level of functioning in the community or long-term health care agency.
- Assess for manifestations of TBI as outlined in [Chart 47-7](#).
- Teach patients with minor head injury and their families to monitor for neurologic changes as listed in [Chart 47-9](#).
- Assess for manifestations of brain tumors as listed in [Chart 47-10](#).
- Recognize that the desired outcome for the patient with a brain tumor is to remove it if possible. Other methods may be used to decrease its size, including chemotherapy and radiation.
- The mainstay of management for patients with brain abscess is systemic antibiotic therapy.

Assessment of the Eye and Vision*M. Linda Workman*<http://evolve.elsevier.com/Iggy/>

Answer Key for NCLEX Examination Challenges and
Decision-Making Challenges

Audio Glossary

Key Points

Review Questions for the NCLEX® Examination

Video Clip: Central Vision

Video Clip: External Eye

Video Clip: Pupil Responses

LEARNING OUTCOMES**Safe and Effective Care Environment**

1. Use aseptic technique when touching the eyelids or external eye structures.
2. Use appropriate technique when instilling eyedrops or eye ointments.
3. Verify that informed consent has been obtained before invasive tests of the eye or vision are performed.

Health Promotion and Maintenance

4. Teach all people about the use of eye protection equipment and strategies.
5. Perform health history and risk assessment for eye and vision problems.
6. Teach patients who have systemic health problems that may affect eye health and vision to adhere to prescribed therapies and to have yearly eye examinations by an ophthalmologist.

Psychosocial Integrity

7. Teach patients and family members about what to expect during tests and procedures to assess vision and eye problems.
8. Provide the opportunity for the patient and family to express their concerns about a possible change in vision.

Physiological Integrity

9. Explain the concept of refraction in relation to how the cornea, lens, aqueous humor, and vitreous humor contribute to vision.
10. Explain the relationship between intraocular pressure and eye health.
11. Use knowledge of anatomy and psychomotor skills when assessing the eye and vision.
12. Explain the eye changes associated with aging and their impact on vision.
13. Interpret the findings of visual acuity by the Snellen chart.

FIG. 48-1 Anatomic features of the eye.

The eye works with the brain to cause vision. Many people consider vision to be the most important sense for sensation and cognition. It is used to assess surroundings, allow independence, warn of danger, appreciate beauty, work, play, and interact with other people.

Vision begins with the eye, where light is changed into nerve impulses. These impulses are sent to the brain, where images are fully perceived. Many systemic conditions, as well as eye problems, affect the eye and change vision temporarily or permanently. Changes in the eye and vision can provide information about the patient's general health status and problems that might occur in self-care.

ANATOMY AND PHYSIOLOGY REVIEW

Structure

The eyeball, a round, ball-shaped organ, is located in the front part of the eye orbit. The **orbit** is the bony socket of the skull that surrounds and protects the eye along with the attached muscles, nerves, vessels, and tear-producing glands.

Layers of the Eyeball

The eye has three layers, or coats (Fig. 48-1). The external layer is the **sclera** (the opaque tissue making up the “white” of the eye) and the transparent cornea on the front of the eye.

The middle layer, or **uvea**, is heavily pigmented and consists of the choroid, the ciliary body, and the iris. The choroid, a dark brown membrane between the sclera and the retina, lines most of the sclera. It has many blood vessels that supply nutrients to the retina.

The ciliary body connects the choroid with the iris and secretes aqueous humor. The **iris** is the colored portion of the external eye; its center opening is the **pupil**. The muscles of the iris contract and relax to control pupil size and the amount of light entering the eye.

The innermost layer is the **retina**, a thin, delicate structure made up of sensory photoreceptors that begin the transmission of impulses to the optic nerve. The retina contains blood vessels and two types of photoreceptors called *rods* and *cones*. The rods work at low light levels and provide peripheral vision. The cones are active at bright light levels and provide color and central vision.

The **optic fundus** is the area at the inside back of the eye that can be seen with an ophthalmoscope. This area contains the **optic disc**, a creamy pink or white depressed area where the fine nerve fibers that synapse with the photoreceptors join together to form the optic nerve and exit the eyeball. The optic disc is sometimes called the “blind spot” because it contains only nerve fibers and no photoreceptor cells. To one side of the optic disc is a small, yellowish pink area called the *macula lutea*. The center of the macula is the *fovea centralis*, where vision is the most acute.

Refractive Structures and Media

Light waves pass through these structures on the way to the retina: cornea, aqueous humor, lens, and vitreous humor. Each structure has a different density, which causes the light waves to bend (**refract**) and focus images on the retina. Together, these structures are the eye's *refracting media*.

The **cornea** is the clear layer that forms the external bump on the front of the eye (see Fig. 48-1). The **aqueous humor** is a clear, watery fluid that fills the anterior and posterior chambers of the eye. Aqueous humor is continually produced by the ciliary processes and passes from the posterior chamber, through the pupil, and into the anterior chamber. This fluid drains through the canal of Schlemm into the blood to maintain a balanced intraocular pressure (IOP), the pressure within the eye (Fig. 48-2).

The **lens** is a circular, convex structure that lies behind the iris and in front of the vitreous body. It is normally transparent and bends the rays of light entering through the pupil so

FIG. 48-2 Flow of aqueous humor.

that they focus properly on the retina. The curve of the lens changes to focus on near or distant objects. A *cataract* is a lens that has lost its transparency.

The **vitreous body** is a clear, thick gel that fills the *vitreous chamber* (the space between the lens and the retina). This gel transmits light and maintains eye shape.

The eye is a hollow organ and must be kept in the shape of a ball for vision to occur. To maintain this shape, the gel in the posterior segment (*vitreous humor*) and the fluid in the anterior segment (*aqueous humor*) must be present in set amounts that apply pressure inside the eye to keep it inflated (McCance et al., 2010). This pressure is known as **intraocular pressure** or **IOP**. IOP has to be just right. If the pressure is too low, the eyeball is soft and collapses, preventing light from getting to the light-sensitive photoreceptors in the back of the eye on the retina. If the pressure becomes too high, the extra pressure compresses capillaries and nerve fibers in the eye. Pressure on retinal blood vessels prevents blood from flowing through them, and as a result the photoreceptors and nerve fibers become hypoxic. Compression of the fine nerve fibers prevents intracellular fluid flow, which also reduces nourishment to the distal portions of these thin nerve fibers. The increased intraocular pressure and resulting hypoxia of the photoreceptors and their synapsing nerve fibers is a condition called *glaucoma*. Continued hypoxia inside the eye result in photoreceptor necrosis and death and permanent nerve fiber damage. With extensive photoreceptor loss and nerve fiber damage, vision is lost and the person is permanently blind.

External Structures

The eyelids are thin, movable skinfolds that protect the eyes, shut out light during sleep, and keep the cornea moist. The upper eyelid is larger than the lower one. The **canthus** is the place where the two eyelids meet at the corner of the eye.

The **conjunctivae** are the mucous membranes of the eye. The palpebral conjunctiva is a thick membrane with many blood vessels that lines the undersurface of each eyelid. The thin, transparent bulbar conjunctiva covers the entire front of the eye.

Tears are produced by a small **lacrimal gland**, which is located in the upper outer part of each orbit (Fig. 48-3). Tears flow across the front of the eye, toward the nose, and into the inner canthus. They drain through the **punctum** (an opening at the nasal side of the lid edges), into the lacrimal duct and sac, and then into the nose through the nasolacrimal duct.

Muscles, Nerves, and Blood Vessels

Six voluntary muscles rotate the eye and coordinate eye movements (Fig. 48-4 and Table 48-1). Coordinated eye movements ensure that the retina of each eye receives an image at the same time so only a single image is seen.

The muscles around the eye are innervated by cranial nerves (CNs) III (oculomotor), IV (trochlear), and VI (abducens). The **optic nerve** (CN II) is the nerve of sight, connecting the optic disc to the brain. Part of the trigeminal nerve (CN V) stimulates the blink reflex when the cornea is touched. The facial nerve (CN VII) innervates the lacrimal glands and muscles controlling lid closure.

The ophthalmic artery brings oxygenated blood to the eye and structures in the orbit. This artery branches to supply blood to the retina. The ciliary arteries supply the sclera, choroid, ciliary body, and iris. Venous drainage occurs through the two ophthalmic veins.

Function

The four eye functions that provide clear images and vision are refraction, pupillary constriction, accommodation, and convergence.

FIG. 48-3 Front view of the eye and adjacent structures.

FIG. 48-4 The extraocular muscles.

Refraction involves bending light rays from the outside world into the eye. The different curved surfaces and refractive media of the eye allow light to pass through to the retina. Each surface and media bends (refracts) light differently to focus an image on the retina. **Emmetropia** is the perfect refraction of the eye: with the lens at rest, light rays from a distant source (20 feet [6 m] or more) are focused into a sharp image on the retina. Fig. 48-5 shows the normal refraction of light within the eye. Images fall on the retina inverted and reversed left to right. For example, an object in the lower nasal visual field strikes the upper outer area of the retina.

TABLE 48-1 FUNCTIONS OF OCULAR MUSCLES

Superior Rectus Muscle

- Together with the lateral rectus, this muscle moves the eye diagonally upward toward the side of the head.
- Together with the medial rectus, this muscle moves the eye diagonally upward toward the middle of the head.

Lateral Rectus Muscle

- Together with the medial rectus, contraction of this muscle holds the eye in a straight position.
- Contracting alone, this muscle turns the eye toward the side of the head.

Medial Rectus Muscle

- Contracting alone, this muscle turns the eye toward the nose.

Inferior Rectus Muscle

- Together with the lateral rectus, this muscle moves the eye diagonally downward toward the side of the head.
- Together with the medial rectus, this muscle moves the eye diagonally downward toward the middle of the head.

Superior Oblique Muscle

- Contracting alone, this muscle pulls the eye downward.

Inferior Oblique Muscle

- Contracting alone, this muscle pulls the eye upward.

FIG. 48-5 Refraction and correction in emmetropia, hyperopia, and myopia.

Errors of refraction are common. **Hyperopia** (farsightedness or *hypermetropia*) occurs when the eye does not refract light enough. As a result, images actually fall (*converge*) behind the retina (see Fig. 48-5). Vision beyond 20 feet is normal, but near vision is poor. Hyperopia is corrected with a convex lens in eyeglasses or contact lenses.

FIG. 48-6 Miosis and mydriasis.

CHART 48-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Eye and Vision Related to Aging

STRUCTURE/ FUNCTION	CHANGE	IMPLICATION
Appearance	Eyes appear “sunken.” Arcus senilis forms. Sclera yellows or appears blue.	Do not use eye appearance as an indicator for hydration status. Reassure patient that this change does not affect vision. Do not use sclera to assess for jaundice.
Cornea	Cornea flattens, which blurs vision.	Encourage older adults to have regular eye examinations and wear prescribed corrective lenses for best vision.
Ocular muscles	Muscle strength is reduced, making it more difficult to maintain an upward gaze or maintain a single image.	Reassure patient that this is a normal happening and to re-focus gaze frequently to maintain a single image.
Lens	Elasticity is lost, increasing the near point of vision (making the near point of best vision farther away). Lens hardens, compacts, and forms a cataract.	Encourage patient to wear corrective lenses for reading. Stress the importance of yearly vision checks and monitoring for when intervention is needed.
Iris	Decrease in ability to dilate results in small pupil size and poor adaptation to darkness.	Teach older adults the need for good lighting for best vision to avoid tripping and bumping into objects.
Pupil	Pupil size is smaller, reducing the ability to see in dim light.	Teach older adults the need for good lighting for best vision to avoid tripping and bumping into objects.
Color vision	Discrimination among greens, blues, and violets decreases.	The patient may not be able to use “dipstick” or other color-indicator monitors of health status.
Tears	Tear production is reduced, resulting in dry eyes, discomfort, and increased risk for corneal damage or eye infections.	Teach patient to use saline eyedrops on a schedule to reduce dryness. Teach patient to increase humidity in the home.

Myopia (nearsightedness) occurs when the eye overbends the light and images converge in front of the retina (see Fig. 48-5). Near vision is normal, but distance vision is poor. Myopia is corrected with a biconcave lens in eyeglasses or contact lenses.

Astigmatism is a refractive error caused by unevenly curved surfaces on or in the eye, especially of the cornea. These uneven surfaces distort vision.

Pupillary constriction and dilation control the amount of light that enters the eye. If the level of light to one or both eyes is increased, both pupils constrict (become smaller). The amount of constriction depends on how much light is available and how well the retina can adapt to light changes. Pupillary constriction is called **miosis**, and pupillary dilation is called **mydriasis** (Fig. 48-6). Drugs can alter pupillary constriction.

Accommodation allows the healthy eye to focus images sharply on the retina whether the image is close to the eye or distant. The process of maintaining a clear visual image when

the gaze is shifted from a distant to a near object is known as **accommodation**. The eye can adjust its focus by changing the curve of the lens.

Convergence is the ability to turn both eyes inward toward the nose at the same time. This action helps ensure that only a single image of close objects is seen.

Eye Changes Associated with Aging

Changes inside the eye cause visual acuity to decrease with age (Touhy & Jett, 2010). Age-related changes of the nervous system and in the eye support structures also reduce visual function (Chart 48-1).

Structural changes occur with aging, including decreased eye muscle tone that reduces the ability to keep gaze focused on a single object. The lower eyelid may relax and fall away from the eye (*ectropion*), leading to dry-eye symptoms.

Arcus senilis, an opaque, bluish white ring within the outer edge of the cornea, is caused by fat deposits (Fig. 48-7). Although very common, this change does not affect vision.

FIG. 48-7 Arcus senilis of the iris.

The clarity and shape of the cornea change with age. After age 65 years, the cornea flattens and the curve of its surface becomes irregular. This change causes or worsens astigmatism and blurs vision.

Fatty deposits cause the sclera to develop a yellowish tinge. A bluish color may be seen as the sclera thins. With age, the iris has less ability to dilate, which leads to difficulty in adapting to dark environments. Older adults may need additional light for reading and other “close up” work and to avoid tripping over objects.

Functional changes also occur with aging. The lens yellows with aging, reducing the ability of the eye to transmit and focus light. The aging lens hardens, shrinks, and loses elasticity. As the lens loses elasticity, the eye reduces accommodation. The **near point of vision** (the closest distance at which the eye can see an object clearly) increases. Near objects, especially reading material, must be placed farther from the eye to be seen clearly. This age-related change is called **presbyopia**. The **far point** (farthest point at which an object can be distinguished) decreases. Together these changes narrow the visual field of an older adult.

As a person ages, general color perception decreases, especially for green, blue, and violet. More light is needed to stimulate the photoreceptors. Intraocular pressure (IOP) is slightly higher in older adults.

Health Promotion and Maintenance

Vision is important to everyday function and quality of life. Many vision and eye problems can be avoided, and others can be corrected or managed if discovered early. Teach all people about eye protection methods, adequate nutrition, and the importance of regular eye examinations.

The risks for cataract formation and for cancer of the eye (ocular melanoma) increase with exposure to ultraviolet (UV) light. Teach people to protect the eyes by using sunglasses that filter UV light whenever they are outdoors. Also explain that UV protection should be used in tanning salons and in work environments that have UV exposure.

Vision can be affected by injury, and eye injury also increases the risk for both cataract formation and glaucoma. Urge all people to wear eye and head protection during work in occupations that involve particulate matter, fluid or blood spatter, high temperatures, or sparks. Eye and head protection should be worn during participation in sports, such as

CHART 48-2 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Using Eyedrops

- Check the name, strength, expiration date, color, and clarity of the eyedrops to be instilled.
- If both eyes are to receive the same drug and one eye is infected, use two separate bottles and carefully label each bottle with “right” or “left” for the correct eye.
- Wash your hands.
- Remove the cap from the bottle.
- Tilt your head backward, open your eyes, and look up at the ceiling.
- Using your nondominant hand, gently pull the lower lid down against your cheek, forming a small pocket.
- Hold the eyedrop bottle (with the cap off) like a pencil, with the tip pointing down, with your dominant hand.
- Rest the wrist holding the bottle against your mouth or upper lip.
- Without touching any part of the eye or lid with the tip of the bottle, gently squeeze the bottle and release the prescribed number of drops into the pocket you have made with your lower lid.
- Gently release the lower lid.
- Close your eye gently (without squeezing the lids tightly).
- Gently press and hold the corner of the eye nearest the nose to close off the punctum and prevent the drug from being absorbed systemically.
- Without pressing on the lid, gently blot away any excess drug or tears with a tissue.
- Keep the eye closed for about 1 minute.
- Place the cap back on the bottle.
- Check to see whether the drug needs to be kept in the refrigerator.
- Wash your hands again.

baseball, or any activity that increases the risk for the eye being hit by objects in motion. Teach people to avoid rubbing the eyes because excessive eye rubbing can traumatize the delicate outer eye surfaces.

Eye infections can lead to vision loss. Although the eye surface is not sterile, the sclera and cornea have no separate blood supply and thus are at risk for infection because the immunities in the blood do not reach these structures. Teach everyone to wash their hands before touching the eye or eyelid. Teach people who use eyedrops about the proper technique to use these drugs (**Chart 48-2**) and to not share eyedrops with others. If an eye has a discharge, teach the patient to use a separate eyedrop bottle for this eye and to wash the unaffected eye before washing the affected eye.

Other health problems, especially diabetes mellitus and hypertension, can have serious adverse effects on vision. Teach patients who have these health problems about the importance of controlling blood glucose levels and managing blood pressure to reduce the risk for vision loss. Explain that yearly consultation with an ophthalmologist is needed to ensure coordination with their regular health care provider to slow or prevent eye complications.

Teach all people who have a refractive error to have an eye examination yearly. Young adults who do not have vision problems may need an eye examination only every 3 to 5 years unless a problem develops. Adults older than 40 years should have an eye examination yearly that includes assessment of intraocular pressure and visual fields, because the risk for both glaucoma and cataract formation increases with age.

CHART 48-3 EYE AND VISION ASSESSMENT

Using Gordon's Functional Health Patterns

Cognitive-Perceptual Pattern

- Do you have any difficulty seeing objects at a distance?
- Do you have any difficulty reading fine print or doing close work?
- Do you wear eyeglasses or contact lenses?
- What type of light do you use for reading?
- Do you wear sunglasses or a hat when outdoors?
- Do you have frequent headaches?
- Have you noticed any change in your ability to see things at night?
- When did you last have your eyes examined?
- Do you go to an ophthalmologist or an optometrist?
- When were you last tested for glaucoma?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

! NURSING SAFETY PRIORITY

Action Alert

Teach people to see a health care provider *immediately* when an eye injury occurs or an eye infection is suspected.

? NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The older adult client asks whether the white ring in the iris of both eyes is a cataract that can be removed to improve her vision. What is the nurse's best response?

- "A cataract forms inside the eye, not on the surface. This growth should be assessed for cancer."
- "This type of ring in the eye gets worse as intraocular pressure increases, leading to glaucoma."
- "The ring is a cataract, and it cannot be removed until it reaches and covers over the pupil."
- "The ring is just a buildup of deposits, not a cataract, and never interferes with vision."

ASSESSMENT METHODS

Patient History

Collect information to determine whether problems with the eye or vision have an impact on ADLs or other daily functions. [Chart 48-3](#) lists questions to ask when assessing the eye and vision.

Age is an important factor to consider when assessing the visual processes and eye structure. The incidence of glaucoma and cataract formation increases with aging. Presbyopia commonly begins in the 40s.

Gender also may be important. For example, retinal detachments are more common in men and dry-eye syndromes are more common in women.

Occupation and leisure activities can affect vision. Ask patients about work and specifically how the eyes are used. In some occupations, such as computer programming, constant exposure to monitor screens may lead to eyestrain. Machine operators are at risk for eye injury because of the high speeds at which particles can be thrown at the eye. Ask the patient who works in industrial settings about the use of protective eyewear, such as goggles. Chronic exposure to infrared or ultraviolet light may cause photophobia and

TABLE 48-2 SYSTEMIC CONDITIONS AND COMMON DRUGS AFFECTING THE EYE AND VISION

Systemic Conditions and Disorders

- Diabetes mellitus
- Hypertension
- Lupus erythematosus
- Sarcoidosis
- Thyroid dysfunction
- Acquired immune deficiency syndrome
- Cardiac disease
- Multiple sclerosis
- Pregnancy

Drugs

- Antihistamines
- Decongestants
- Antibiotics
- Opioids
- Anticholinergics
- Cholinergic agonists
- Sympathomimetics
- Oral contraceptives
- Chemotherapy agents
- Corticosteroids
- Carbonic anhydrase inhibitors
- Beta blockers

cataract formation. Teach the patient about the use of eye protection during work.

Ask whether the patient plays sports, the type of sport played, and whether eye protection is used. Even a blow to the head near the eye, such as with a baseball, can damage external eye structures, the eye, the connections with the brain, or the area of the brain where vision is perceived.

Systemic health problems can affect vision. Check whether the patient has any condition listed in [Table 48-2](#). Ask about past accidents, injuries, surgeries, or blows to the head that may have led to the present problem. Specifically ask about previous laser surgeries because patients often do not classify laser treatment as surgery.

Drugs, even systemic drugs, can affect vision and the eye (see [Table 48-2](#)). Ask about the use of any prescription or over-the-counter drugs, especially decongestants and antihistamines, which tend to dry the eye and may increase intraocular pressure (IOP). Many patients do not consider over-the-counter eyedrops to be drugs. Record the name, strength, dose, and scheduling for all drugs the patient uses. Ocular effects from drugs include **pruritus** (itching), foreign body sensation, redness, tearing, **photophobia** (sensitivity to light), and the development of cataracts or glaucoma.

Nutrition History

Because some ocular problems are caused by or made worse with vitamin deficiencies, ask the patient about his or her food choices. For example, vitamin A deficiency can cause eye dryness, keratomalacia, and blindness. However, nutrients and antioxidants such as lutein and beta carotene may help maintain retinal function. A diet rich in fruit and red, orange, and dark green vegetables is important to eye health. Teach all people to eat five to ten servings of these foods daily.

Family History and Genetic Risk

Ask about a family history of eye problems. Some conditions, such as a refractive error, show a familial tendency. Some genetic problems lead to visual impairment in adulthood (Nussbaum et al., 2007). When a patient tells you that other relatives, especially first-degree relatives (parents, siblings, and children), have eye problems, record the gender of the affected person, his or her relationship to the patient, the exact nature of the problem, and the age that the problem was first noted.

Current Health Problems

Ask the patient about the onset of visual changes. Did the change occur rapidly or slowly? Determine whether the symptoms are present to the same degree in both eyes.

Ask these questions if ocular injury or eye trauma is involved:

- How long ago did the injury occur?
- What was the patient doing when it happened?
- If a foreign body was involved, what was its source?
- Was any first aid administered at the scene? If so, what actions were taken?

! NURSING SAFETY PRIORITY

Critical Rescue

Notify the ophthalmologist immediately for any patient who has a sudden or persistent loss of vision within the past 48 hours, eye trauma, a foreign body in the eye, or sudden ocular pain.

Physical Assessment

Inspection

Look for head tilting, squinting, or other noticeable actions that indicate the patient is compensating to try to attain clear vision. For example, patients with double vision may cock the head to the side to focus the two images into one or they may close one eye to see more clearly.

Assess for symmetry in the appearance of the eyes. Check the eyes to determine whether they are equal distance from the nose, are the same size, and have the same degree of prominence. Assess the eyes for their placement in the orbits and for symmetry of movement. **Exophthalmos** (*proptosis*) is protrusion of the eye. **Enophthalmos** is the sunken appearance of the eye.

Examine the eyebrows and eyelashes for hair distribution, and determine the direction of the eyelashes. Eyelashes normally point outward and away from the eyelid. Assess the eyelids for **ptosis** (drooping), redness, lesions, or swelling. The lids normally close completely, with the upper and lower lid edges touching. When the eyes are open, the upper lid covers a small portion of the iris. The edge of the lower lid lies below the line between the cornea and sclera. No sclera should be visible between the eyelid and the iris.

Scleral and corneal assessment requires a penlight. Examine the sclera for color; it is usually white. A yellow color may indicate jaundice or systemic problems. In dark-skinned people, the normal sclera may appear yellow and small, pigmented dots may be visible (Jarvis, 2012).

The cornea is best observed by directing a light at it from the side using several angles. The cornea should be transparent, smooth, shiny, and bright. Any cloudy areas or specks may be the result of accidents or injuries.

Assess the blink reflex by bringing a fist quickly toward the patient's face; patients with vision will blink. This reflex can also be assessed by expelling a syringe full of air toward the eyes. The patient blinks if the reflex is intact.

Pupillary assessment involves examining each pupil separately and comparing the results. This examination is also part of a rapid neurologic assessment. The pupils are usually round and of equal size. About 5% of people normally have a noticeable difference in the size of their pupils, which is known as **anisocoria** (Jarvis, 2012). Pupil size varies in people exposed to the same amount of light. Pupils are smaller in older adults. People with myopia have larger pupils. People with hyperopia have smaller pupils. The normal pupil diameter is between 3 and 5 mm. Smaller pupils reduce vision in low light conditions.

Observe the pupils for their response to light. Increasing light causes constriction, whereas decreasing light causes dilation. Constriction of both pupils is the normal response to direct light and to accommodation. Assess pupillary reaction to light by asking the patient to look straight ahead while you quickly bring the beam of a penlight in from the side and direct it at the right pupil. Constriction of the right pupil is a direct response to shining the penlight into that eye. Constriction of the left pupil when light is shined at the right pupil is known as a **consensual response**. Assess the responses for each eye. (You may see the abbreviation "PERRLA" in a patient's medical record, which stands for *pupils equal, round, reactive to light, and accommodative*.)

Evaluate each pupil for speed of reaction. The pupil should immediately constrict when a light is directed at it. This rapid response is termed *brisk*. If the pupil takes more than 1 second to constrict, the response is termed *sluggish*. Pupils that fail to react are termed *nonreactive* or *fixed*. Compare the reactivity speed of right and left pupils, and document any difference.

To assess for accommodation, hold your finger about 18 cm from the patient's nose and move it toward the nose. The patient's eyes normally converge during this movement, and the pupils constrict equally. When accommodation stops, the pupils first enlarge and then return to their normal size.

Vision Testing

Vision is measured by various tests. First test each eye separately, and then test both eyes together. Patients who wear corrective lenses are tested both without and with their lenses.

Visual acuity tests measure both distance and near vision. The Snellen chart, or "eye chart," is a simple tool to measure distance vision. This chart has letters, numbers, pictures, or a single letter presented in various positions (Fig. 48-8). The chart with one letter in different positions is used for patients who cannot read, who do not speak the language used at the facility, or who cannot speak but do have adequate cognition. Have the patient stand 20 feet from the chart, cover one eye, and use the other eye to read the line that appears most clear. If the patient can do this accurately, ask him or her to read the next lower line. Repeat this sequence to the last line on which the patient can correctly identify most characters. Repeat the procedure with the other eye. Record findings as a comparison between what the patient can read at 20 feet and the distance at which a person with normal vision can read the same line. For example, 20/50 means that the patient can see at 20 feet from the chart what a "healthy eye" can see at 50 feet.

FIG. 48-8 A typical Snellen chart.

For patients who are in a confined space that does not permit a 20-foot distance to the eye chart or who cannot see the 20/400 character, assess visual acuity by holding fingers in front of their eyes and asking them to count the number of fingers. Acuity is recorded as “count fingers vision at 5 feet,” or the farthest distance at which fingers are counted correctly.

Patients who cannot count fingers are tested for hand motion (HM) acuity. Stand about 2 to 3 feet in front of the patient. Ask him or her to cover the eye not being tested. Direct a light onto your hand from behind the patient. Demonstrate the three possible directions in which the hand can move during the test (stationary, left-right, or up-down). Move your hand slowly (1 second per motion), and ask the patient, “What is my hand doing now?” Repeat this procedure five times. Visual acuity is recorded as HM at the farthest distance at which most of the hand motions are identified correctly.

If the patient cannot detect hand movement, test acuity by measuring light perception (LP). Ask the patient first to cover the left eye. In a darkened room, direct the beam of a penlight at the patient’s right eye from a distance of 2 to 3 feet for 1 to 2 seconds. Instruct the patient to say “on” when the beam of light is perceived and “off” when it is no longer detected. If the patient identifies the presence or absence of light three times correctly, acuity is recorded as LP.

Near vision is tested for patients who have difficulty reading without using glasses or other means of vision

FIG. 48-9 Checking extraocular movements in the six cardinal positions indicates the functioning of cranial nerves III, IV, and VI.

correction. Use a small, handheld miniature chart called a *Rosenbaum Pocket Vision Screener* or a *Jaeger card*. Ask the patient to hold the card 14 inches away from his or her eyes and read the characters. Test each eye separately and then together. Record the value of the lowest line on which the patient can identify more than half the characters.

Visual field testing is used to determine the degree of peripheral vision. It can be performed formally with a computerized machine or informally with a “confrontation test” for a crude but rapid check of peripheral vision. During the confrontation test, sit facing the patient and ask him or her to look directly into your eyes while you look into the patient’s eyes. Cover your right eye and have the patient cover his or her left eye so that you both have the same visual field. Then move a finger or an object from a nonvisible area into the patient’s line of vision. The patient with normal peripheral vision should notice the object at about the same time you do. Repeat this examination by covering your left eye and the patient covering his or her right eye. Note any areas in which you can see but the patient cannot.

Extraocular muscle function is assessed using the corneal light reflex and the six cardinal positions of gaze. These tests not only assess smoothness of eye movements but also test the function of cranial nerves III, IV, and VI.

The corneal light reflex determines alignment of the eyes. After asking the patient to stare straight ahead, shine a penlight at both corneas from a distance of 12 to 15 inches. The bright dot of light reflected from the shiny surface of the cornea should be in a symmetric position (e.g., at the 1 o’clock position in the right eye and at the 11 o’clock position in the left eye). An asymmetric reflex indicates a deviating eye and possible muscle weakness.

Use the six cardinal positions of gaze to assess muscle function (Fig. 48-9). The eye will not turn to a particular position if the muscle is weak or if the controlling nerve is affected. Ask the patient to hold his or her head still and to move only the eyes to follow a small object. Move the object to the patient’s right (lateral), upward and right (temporal), down and right, left (lateral), upward and left (temporal), and down and left (see Fig. 48-9). While the patient moves the eyes to these positions, note whether both eyes move in a parallel manner and any deviation of movement. **Nystagmus**, an involuntary and rapid twitching of the eyeball, is a normal finding for the far lateral gaze. It may also be caused by abnormal nerve function.

Color vision is usually tested using the *Ishihara chart*, which shows numbers composed of dots of one color within a circle of dots of a different color (Fig. 48-10). Test each eye separately by asking the patient what numbers he or she sees on the chart. Reading the numbers correctly indicates normal color vision.

FIG. 48-10 An Ishihara chart for testing color vision.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which client assessment finding does the nurse report to the health care provider immediately?

- A. The left pupil is slightly smaller than the right pupil.
- B. Both eyes twitch when the client looks to the far lateral gaze position.
- C. The right pupil does not change size when a light is shined directly at it.
- D. The lowest line the client can read clearly at 20 feet on the Snellen chart is marked 50 feet.

Psychosocial Assessment

A patient with changes in visual perception may be anxious about possible vision loss. Patients with severe visual defects may be unable to perform ADLs or engage in some leisure activities. Dependency resulting from reduced vision can affect self-esteem. Ask the patient how he or she feels about the vision changes, and assess the effectiveness of coping techniques. Discuss these concerns with the family to determine available support. Also assess the patient's knowledge and use of services for the visually impaired. Provide information about local resources and services for reduced vision.

Diagnostic Assessment

Laboratory Assessment

Cultures of corneal or conjunctival swabs and scrapings help diagnose infections. Obtain a sample of the exudate for culture before antibiotics or topical anesthetics are instilled. Take swabs from the conjunctivae and any ulcerated or inflamed areas.

Imaging Assessment

Computed tomography (CT) is a useful diagnostic tool for looking at the eyes, the bony structures around the eyes, and the extraocular muscles. It is also used for detecting tumors

in the orbital space. Contrast dye is used unless trauma is suspected. Tell the patient that this test is not painful but does require that he or she be positioned in a confined space and must keep the head still during the procedure.

Magnetic resonance imaging (MRI) is often used to examine the orbits and the optic nerves and to evaluate ocular tumors. MRI cannot be used to evaluate injuries involving metal in the eyes. *Metal in the eye is an absolute contraindication for MRI.*

Radioisotope scanning is used to locate tumors and lesions. Isotope studies differentiate an intraocular tumor from a hemorrhage, especially in the choroid layer.

After signing an informed consent form, the patient receives a tracer dose of the radioactive isotope, either orally or by injection. He or she is asked to lie still and breathe normally. The scanner measures the radioactivity emitted by the radioactive atoms concentrated in the area being studied. Sedation may be used for patients who are anxious.

Assure the patient that the amount of radioisotope used is small and that he or she is not radioactive. No other special follow-up care is required.

Ultrasonography is used to examine the orbit and eye with high-frequency sound waves. This noninvasive test aids in the diagnosis of trauma, intraorbital tumors, proptosis, and choroidal or retinal detachments. It is also used to determine gross outline changes in the eye and the orbit in patients with cloudy corneas or lenses that reduce direct examination of the fundus. Ultrasonography helps calculate the length of the eye, one of the measurements used to determine the strength of the intraocular lens implant needed after cataract removal.

Inform the patient that this test is painless because anesthetic drops are instilled into the lower lid. He or she sits upright with the chin in the chin rest. The probe is touched against the patient's anesthetized cornea, and sound waves are bounced through the eye. The sound waves create a reflective pattern on a computer screen that can be examined for abnormalities. No special follow-up care is needed. Remind the patient not to rub or touch the eye until the effects of the anesthetic drops have worn off.

Other Diagnostic Assessment

Many tests are used to examine specific eye structures but are not needed for routine vision assessment. Such tests may be indicated for those with special risks, symptoms, or exposures. These tests are performed only by physicians, optometrists, or advanced practice nurses.

Slit-lamp examination magnifies the anterior eye structures (Fig. 48-11). The patient leans on a chin rest to stabilize the head. A narrow beam (slit) of light is aimed so that only a narrow segment of the eye is brightly lighted. The examiner can then locate the position of any abnormality in the cornea, lens, or anterior vitreous humor.

Corneal staining consists of placing fluorescein or other topical dye into the conjunctival sac. The dye outlines irregularities of the corneal surface that are not easily visible. This test is used for corneal trauma, problems caused by a contact lens, or the presence of foreign bodies, abrasions, ulcers, or other corneal disorders.

This procedure is noninvasive and is performed under aseptic conditions. The dye is applied topically to the eye, and the eye is then viewed through a blue filter. Nonintact areas of the cornea stain a bright green color.

FIG. 48-11 Slit-lamp ocular examination.

Tonometry measures intraocular pressure (IOP) using a tonometer. This instrument applies pressure to the outside of the eye until it equals the pressure inside the eye as indicated when the cornea begins to indent. Normal IOP readings have always been considered to range from 10 to 21 mm Hg; however, this number is not absolute and must be considered along with corneal thickness. The thickness of the cornea affects how much pressure must be applied before indentation occurs. For example, a person with a thicker cornea will have a higher tonometer reading that may falsely indicate increased IOP. A person with a thinner-than-normal cornea may have a low tonometer reading even when higher IOP is present.

About 5% of patients with healthy eyes have a slightly higher pressure. Tonometer readings are indicated for all patients older than 40 years. Adults with a family history of glaucoma should have their IOP measured once or twice a year. The most common method to measure IOP by an ophthalmologist is the Goldman's applanation tonometer used with a slit lamp (Fig. 48-12). This method involves direct eye contact. Another instrument, the Tono-Pen (Fig. 48-13), is designed for use by patients in the home to measure IOP daily.

Intraocular pressure varies throughout the day. It is often higher in the morning but may peak at any time of the day. Therefore always document the time of IOP measurement and teach patients who are measuring IOP at home to perform the measurement at the same time or times each day.

Ophthalmoscopy allows viewing of the eye's external and interior structures with an instrument called an *ophthalmoscope*. This examination can be performed by any nurse but usually is performed by a physician, advanced practice nurse, or physician assistant. It is easiest to examine the fundus when the room is dark, because the pupil will dilate. Stand on the same side as the eye being examined. Tell the patient to look straight ahead at an object on the wall behind you. Placing your thumb on the patient's eyebrow can help you know the distance from the ophthalmoscope to the patient. Hold the ophthalmoscope firmly against your face, and align it so that your eye sees through the sight hole (Fig. 48-14).

When using the ophthalmoscope, move toward the patient's eye from about 12 to 15 inches away and to the side

Goldman's applanation tonometer

FIG. 48-12 Use of Goldman's applanation tonometer and a slit lamp to measure intraocular pressure (IOP).

FIG. 48-13 The Tono-Pen.

FIG. 48-14 Proper technique for direct ophthalmoscopic visualization of the retina.

of his or her line of vision. As you direct the ophthalmoscope at the pupil, a red glare (**red reflex**) should be seen in the pupil as a reflection of the light on the retina. An absent red reflex may indicate a lens opacity or cloudiness of the vitreous. Move toward the patient's pupil while following the red

TABLE 48-3 STRUCTURES ASSESSED BY DIRECT OPHTHALMOSCOPY**Red Reflex**

reflex. The retina should then be visible through the ophthalmoscope. Examine the optic disc, optic vessels, fundus, and macula. Table 48-3 lists the features that can be observed in each structure.

The use of an ophthalmoscope may make a confused patient or one who does not understand the language more anxious. When working with a patient who does not speak the language used at the facility, use an interpreter, when possible, to ensure the patient's understanding and cooperation with the examination.

! NURSING SAFETY PRIORITY**Action Alert**

Avoid using an ophthalmoscope with a confused patient.

Fluorescein angiography, which is performed by a physician or advanced practice nurse, provides a detailed image of eye circulation. Photographs are taken in rapid succession after the dye is given IV. This test is useful for assessing problems of retinal circulation (e.g., diabetic retinopathy, retinal hemorrhage, and macular degeneration) or for diagnosing intraocular tumors.

Explain the procedure to the patient, and instill mydriatic eyedrops (cause pupil dilation) 1 hour before the test. Chart 48-4 lists the best practice for correct eyedrop instillation. Check that the informed consent has been signed by the patient or responsible person. Warn that the dye may cause the skin to appear yellow for several hours after the test. The stain is eliminated through the urine, which also changes color.

Intravenous access must be obtained. After the needle is in the vein, 5 mL of a 10% solution of fluorescein is injected.

CHART 48-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Instillation of Eyedrops**

- Check the name, strength, expiration date, color, and clarity of the eyedrops to be instilled.
- Check to see whether only one eye is to have the drug or if both eyes are to receive the drug.
- If both eyes are to receive the same drug and one eye is infected, use two separate bottles and carefully label each bottle with "right" or "left" for the correct eye.
- Wash your hands.
- Put on gloves if secretions are present in or around the eye.
- Explain the procedure to the patient.
- Have the patient sit in a chair, and you stand behind the patient.
- Ask the patient to tilt the head backward, with the back of the head resting against your body and looking up at the ceiling.
- Gently pull the lower lid down against the patient's cheek, forming a small pocket.
- Hold the eyedrop bottle (with the cap off) like a pencil, with the tip pointing down.
- Rest the wrist holding the bottle against the patient's cheek.
- Without touching any part of the eye or lid with the tip of the bottle, gently squeeze the bottle and release the prescribed number of drops into the pocket you have made with the patient's lower lid.
- Gently release the lower lid.
- Tell the patient to close the eye gently (without squeezing the lids tightly).
- Gently press and hold the corner of the eye nearest the nose to close off the punctum and prevent the drug from being absorbed systemically.
- Without pressing on the lid, gently blot away any excess drug or tears with a tissue.
- Remove your gloves, and place the cap back on the bottle.
- Ask the patient to keep the eye closed for about 1 minute.
- Wash your hands again.

A digital camera is set up with equipment to photograph retinal and choroidal blood vessels as the dye passes through them. The results can be viewed immediately on a computer screen. The procedure takes only a few minutes because the vessels fill quickly.

! DECISION-MAKING CHALLENGE**Patient-Centered Care; Safety; Teamwork and Collaboration**

The patient is a 75-year-old woman from Mexico who was brought to the clinic by her daughter. The patient speaks no English, and the daughter serves as her interpreter. The daughter explains that even though her mother wears nonprescription glasses that she bought at the drugstore to do close work, she says that everything is always blurry. A complete eye examination is planned with an eye chart, an ophthalmoscope, a slit lamp, and tonometry.

1. What type of Snellen chart would be most appropriate for this patient? Explain your choice.
2. Should the daughter be allowed to stay with her? Why or why not? After an explanation by her daughter of what is expected of her, the patient participates in the Snellen chart test and "reads" the 70-foot line correctly but is incorrect on the 50-foot line. She then sits quietly and cooperates during the examination with the ophthalmoscope. However, when a slit-lamp examination is attempted, the patient keeps moving her head to the side and shouts "no, no, no," and tells her daughter that she is afraid of this big machine.
3. Is a slit-lamp examination important to perform for this patient? Why or why not?
4. What technique or techniques could be used to allay her fears?

Encourage patients to drink fluids to help eliminate the dye. Remind them that any yellow or green staining of the skin will disappear in a few hours. After the test, the urine will be bright green until the dye is excreted. Teach the patient to wear dark glasses and avoid direct sunlight until pupil dilation returns to normal, because the bright light will cause eye pain.

Electroretinography is the process of graphing the retina's response to light stimulation. This test is helpful in detecting and evaluating blood vessel changes from disease or drugs. The graph is obtained by placing a contact lens electrode on an anesthetized cornea. Lights at varying speeds and intensities are flashed, and the neural response is graphed. The measurement from the cornea is identical to the response that would be obtained if electrodes were placed directly on the retina.

Perimetry is a commonly used test to screen the visual fields. During this computerized test, the patient is asked to

look straight ahead and then indicate, by pressing a control button, when a moving light enters the peripheral vision. This process draws a "map" of the person's peripheral vision and any deficits.

Gonioscopy is a test performed when a high IOP is found and determines whether open angle or closed angle glaucoma is present. It uses a special lens that eliminates the corneal curve, is painless, and allows visualization of the angle where the iris meets the cornea.

Laser imaging of the retina and optic nerve creates a three-dimensional view of the back of the eye. It is commonly used for those people with ocular hypertension or who are at risk for glaucoma from other problems. This type of computerized examination assesses the thickness and contours of the optic nerve and retina for changes that indicate damage as a result of high IOP. This type of test can be used serially for a person at risk for glaucoma to detect early changes and indicate when intervention is needed.

NURSING CONCEPT REVIEW

What should you expect to NOTICE in a patient with adequate sensation related to the eye and vision?

Physical Assessment

- Eyes are symmetric on the face on a line just about even with the tops of the ears.
- Eyes are clear with no drainage or open areas.
- Patient does not squint or tilt the head.
- Patient does not close one eye to read or see at a distance.
- Patient startles when a sudden move is made at the face.
- Patient blinks 5 to 10 times per minute.
- Pupils are the same size in each eye.

- Both pupils constrict when a light is shined at only one eye.
- Appearance is neat with buttons properly buttoned and hair combed or brushed.
- Patient comments on the presence of art or unusual visual objects in the immediate environment.
- Patient walks without hesitation into a room without bumping into objects in his or her path.

Psychological Assessment

- Patient is oriented and not confused.
- Patient makes eye contact when speaking.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Wash your hands before moving a patient's eyelids.
- If a patient has discharge from one eye, examine the eye without the discharge first.
- Wear gloves when examining an eye with drainage.
- Avoid using an ophthalmoscope on a confused patient.

Health Promotion and Maintenance

- Teach patients not to rub their eyes.
- Identify patients at risk for eye injury as a result of work environment or leisure activities.
- Urge all patients to wear eye protection when they are performing yard work, working in a woodshop or metal

shop, using chemicals, or are in any environment in which drops or particulate matter is airborne.

Psychosocial Integrity

- Provide opportunities for the patient and family to express their concerns about a possible change in vision status.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.

Physiological Integrity

- Ask the patient about vision problems in any other members of the family, because some vision problems have a genetic component.
- Test the visual acuity of both eyes immediately of any person who experiences an eye injury or any sudden change in vision.

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Use aseptic technique when performing an eye examination or instilling drugs into the eye.
2. Apply the principles of infection control when caring for a patient with an eye infection.
3. Orient the patient with reduced vision to his or her immediate environment.
4. Ensure that all members of the health care team are aware of a patient's visual limitations and need for assistance.

Health Promotion and Maintenance

5. Teach all people, especially those older than 40 years, to have an annual eye examination including measurement of intraocular pressure.
6. Teach patients and family members how to correctly instill ophthalmic drops and ointment into the eye.
7. Teach the patient and family how to alter the home environment for patient safety.

Psychosocial Integrity

8. Teach patients and family members about what to expect during procedures to correct vision and eye problems.

9. Provide opportunities for the patient and family to express concerns about a change in vision.
10. Refer the patient with reduced vision to local services for the blind.
11. Teach the patient with reduced vision about techniques for performing ADLs and self-care independently.

Physiological Integrity

12. Explain the consequences of increased intraocular pressure (IOP).
13. Identify common actions, conditions, and positions that increase IOP.
14. Prioritize educational needs for the patient after cataract surgery with lens replacement.
15. Prioritize educational needs for patients with primary open-angle glaucoma.
16. Describe the mechanisms of action and nursing implications of drug therapy for glaucoma.

Vision is affected by many factors and problems. Some problems occur gradually, such as cataracts, and others can result from an acute insult or illness. Even when reduced vision is temporary, the patient must make some changes in function or lifestyle.

EYELID DISORDERS

The eyelid is composed of thin skin attached to small muscles. It protects the eye surface and spreads tears. Problems can occur with changes in the structure, function, or position of the eyelid. Lid structure may also be altered by age.

FIG. 49-1 Application of ophthalmic ointment.

Blepharitis

Blepharitis, an inflammation of the eyelid edges, occurs most often in the older adult and those with dry eye syndrome (see the Keratoconjunctivitis Sicca section, p. 1056). Reduced tear production often leads to bacterial infection of the eye, because tears inhibit bacterial growth.

Patients usually have itchy, red, and burning eyes. **Seborrhea** (greasy, itchy scaling) of the eyebrows and eyelids is often present. Greasy scales and matting may be seen where the eyelashes exit the eyelid.

Blepharitis is controlled with eyelid care using warm, moist compresses followed by gentle scrubbing with dilute baby shampoo. Instruct the patient to avoid rubbing the eyes, because if infection is present, this action can spread the infection to other eye structures.

Entropion and Ectropion

An **entropion** is the turning inward of the eyelid causing the lashes to rub against the eye. Entropion can be caused by eyelid muscle spasms or by scarring and deformity of the eyelid after trauma. It occurs often among older adults because of age-related loss of tissue support.

The patient usually reports “feeling something in my eye.” Pain and tears may also be present. The eyelid is turned inward, and the conjunctiva is red. Corneal abrasion may result from constant irritation.

Surgery corrects eyelid position by either tightening the orbicular muscles and moving the eyelid to a normal position or by preventing inward rotation of the eyelid. After surgery, the eye is covered with a patch and the patient is discharged a few hours later.

Demonstrate instillation of eyedrops, and evaluate the patient’s ability to instill the drops. Instruct the patient to leave the patch in place until he or she is seen by the ophthalmologist and to report any pain or drainage under the patch. Teach the patient or family member how to clean the suture line with a cotton swab and the prescribed solution. A small amount of antibiotic ointment may be applied (Fig. 49-1). **Chart 49-1** describes how to apply ophthalmic ointment. **Chart 49-2** lists information on common ophthalmic drugs for eye inflammation and infection.

An **ectropion** is the turning outward and sagging of the eyelid, which often occurs with aging, caused by muscle

CHART 49-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Instillation of Ophthalmic Ointment

- Check the name, strength, and expiration date of the ointment to be instilled. Be sure it is an ophthalmic (eye) preparation and not a general topical ointment.
- Check to see whether only one eye is to receive the drug or if both eyes are to receive the drug.
- If both eyes are to receive the same drug and one eye is infected, use two separate tubes and carefully label each tube with “right” or “left” for the correct eye.
- Wash your hands and put on gloves.
- Explain the procedure to the patient.
- Have the patient sit in a chair, and you stand behind the patient.
- Ask the patient to tilt the head backward, with the back of the head resting against your body and looking up at the ceiling.
- Gently pull the lower lid down against the patient’s cheek, forming a small pocket.
- Hold the tube (with the cap off) like a pencil, with the tip pointing down.
- Rest the wrist holding the tube against the patient’s cheek.
- Without touching any part of the eye or lid with the tip of the tube, gently squeeze the tube and release about a $\frac{1}{4}$ - to $\frac{1}{2}$ -inch thin strip of ointment into the pocket you have made with the patient’s lower lid. Start at the nose side of the pocket, and move toward the outer edge of the pocket.
- Gently release the lower lid.
- Tell the patient to close the eye gently (without squeezing the lids tightly).
- With the patient’s eye closed, gently wipe away any excess ointment with a tissue.
- Tell the patient that sight in that eye will be blurred while the ointment is present in the eye and that he or she should not drive or operate heavy machinery until the ointment is removed.
- Remove your gloves, and place the cap back on the tube.
- Ask the patient to keep the eye closed for about 1 minute.
- Wash your hands again.
- To remove ointment from the eye, wear gloves if drainage is present.
- Then ask the patient to close the eye; wipe the closed lids with a clean tissue from the corner of the eye nearest the nose outward. If you are wiping the same eye twice, use a different area of the tissue or use a new one.

! NURSING SAFETY PRIORITY

Drug Alert

Check the route of administration for ophthalmic drugs. Most are administered as eye instillation route, not the oral route. Administering these drugs orally can cause systemic side effects in addition to not having a therapeutic effect on the eye.

relaxation or weakness. This lid position reduces the washing action of tears, leading to corneal drying and ulceration.

Patients often have constant tears and a sagging lower eyelid. Surgery can restore lid alignment. After surgery, the eye is covered with a patch and the patient is discharged. Nursing care is the same as for an entropion.

Hordeolum

A **hordeolum**, or *stye*, is an infection of the sweat glands in the eyelid (external hordeolum) or of the eyelid sebaceous gland (internal hordeolum). A red, swollen, tender area occurs on the skin surface side of the eyelid. The most

common causative organisms are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus*. The hordeolum usually affects only one eyelid at a time. Vision is not affected.

Small, beady, swollen areas may be on the skin side of the eyelid or on the conjunctival side of the eyelid. Pain occurs as the hordeolum fills with purulent material.

Management includes applying warm compresses four times a day and an antibacterial ointment. When the lesion opens, the pus drains and the pain subsides.

Nursing interventions include instructing the patient how to apply compresses. [Chart 49-3](#) describes the proper technique for application of an eye compress.

After compresses have been applied, instill antibiotic ointment. Advise the patient that ointments may cause blurred vision, and teach him or her to remove the ointment from the eyes before driving or operating machinery. To remove the ointment, teach the patient to close the eye and then gently wipe the closed eyelid from the nasal side of the eye outward.

CHART 49-2 COMMON EXAMPLES OF DRUG THERAPY

Eye Inflammation and Infection

DRUG	NURSING INTERVENTIONS*†	RATIONALES
Topical Anesthetics		
Proparacaine HCl, or proxymetacaine (AK-Taine, Alcaine, Ocu-Caine, Ophthetac)	Remind the patient not to rub or touch the eye while it is anesthetized.	Touching may injure the eye.
Tetracaine HCl, cocaine HCl (Pontocaine)	Patch the eye if the patient leaves the facility before the anesthetic wears off. Instruct the patient not to use discolored solution. Teach the patient to store the bottle tightly closed.	The use of a patch prevents injury, such as corneal abrasion. Discoloration is a sign of altered drug composition. Air may cause drug contamination and oxidation.
Topical Steroids		
Prednisolone acetate (Ocu-Pred, Ophtho-Tate 🍁)	Tell the patient to shake the bottle vigorously before use.	Drug is a suspension; shaking is required to distribute the drug evenly in the solution.
Prednisolone phosphate (Inflamase)	Teach the patient to check for corneal ulceration (pain, reduced vision, secretions).	Steroid use predisposes the patient to local infection.
Dexamethasone (Dexair, Dextotic, Maxidex)	Warn the patient not to share eyedrops with others.	Disease transmission is possible when sharing eyedrops.
Betamethasone (Betnesol)		
Fluorometholone (Fluor-Op, Liquifilm)		
Anti-Infective Agents		
Gentamicin (Genoptic, Gentak Alcomycin 🍁)	Teach the patient the importance of using the drug exactly as prescribed, even if he or she needs to use it hourly.	Bacterial and fungal eye infections worsen rapidly and can lead to blindness if not treated adequately.
Tobramycin (Tobrex)	Teach the patient how to clean exudate from the eyes before using drops.	Cleansing decreases the risk for contaminating the drug and increases contact of the conjunctiva with the drug.
Ciprofloxacin (Ciloxan)		
Erythromycin (Ilotycin)		
Chlortetracycline (Aureomycin)		
Sulfisoxazole (Gantrisin)		
Ofloxacin (Ocuflox)	Reinforce the importance of completing the prescribed drug regimen.	Adherence is critical to maintain a therapeutic level of drug.
Levofloxacin (Quixin)		
Antibiotic-Steroid Combinations		
Tobramycin with dexamethasone (TobraDex)	This is the same as for the general anti-infective agents alone and for the steroids alone.	This is the same as for the general anti-infective agents alone and for the steroids alone.
Neomycin sulfate with polymyxin B sulfate and dexamethasone (Maxitrol)		
Topical Antiviral Agents		
Trifluridine (Viroptic)	Teach the patient to refrigerate the drug and protect it from light.	Drug stability is affected by warm temperatures and light.
Vidarabine (Vira-A)	Teach the patient to assess for itching lids and burning eyes.	Sensitivity to these drugs is common.
Antifungal Agents		
Amphotericin B	Teach the patient to assess for itching lids and burning eyes.	Sensitivity to these drugs is common.
Natamycin (Natacyn)		
Nonsteroidal Anti-Inflammatory Agents		
Flurbiprofen (Ocufen)	Teach the patient to check for bleeding in the eye.	These drugs disrupt platelet aggregation.
Diclofenac (Voltaren)	Teach the patient not to wear soft contact lenses during therapy with these drugs.	These drugs interact with contact lens materials and increase the risk for infection.
Bromfenac (Xibrom)		
Ketorolac (Acular)		

*When instilling eyedrops, teach patients to use nasal punctal occlusion to reduce the risk for systemic absorption and side effects.

†When more than one topical ophthalmic drug is prescribed, teach patients to separate the instillation of each drug by 10-15 minutes (or package recommendations).

CHART 49-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Application of an Ocular Compress

- Wash your hands.
- Fold a clean washcloth into fourths.
- Soak the washcloth with running tap water that is warm to your inner wrist. (If cool compresses are needed, follow the same steps using cold running tap water.)
- Place the cloth over your closed eye.
- Keep the cloth in place with minimal pressure until the cloth cools (or warms, if cool compresses are prescribed).
- Refold the washcloth so that a different “fourth” will be held against the eye.
- Resoak the cloth with running tap water.
- Repeat applications three times for as many times each day as prescribed by your health care provider.

Chalazion

A **chalazion** is an inflammation of a sebaceous gland in the eyelid. It begins with redness and tenderness, followed by a gradual *painless* swelling. Later, redness and tenderness are not present. Most chalazia protrude on the inside of the eyelid. The patient has eye fatigue, light sensitivity, and excessive tears.

Management includes applying warm compresses four times a day, followed by instillation of ophthalmic ointment. If the chalazion is large enough to affect vision or is cosmetically displeasing, it may be removed surgically.

After surgery, antibiotic ointment is instilled and the eye is covered with a patch. Best practices for application of a nonpressure eye patch are described in [Chart 49-4](#).

Instruct the patient to leave the eye patch in place for about 6 hours and then remove the patch and apply warm, wet compresses. Antibiotic eyedrops are instilled after use of

CHART 49-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Application of an Eye Patch

Nonpressure Eye Patch

1. Assemble the equipment:
 - Eye patch
 - Skin preparation pad
 - Nonallergenic paper tape
2. Explain the procedure to the patient.
3. Wash your hands.
4. Apply a skin preparation to the patient's forehead and cheek.
5. Instruct the patient to close both eyes gently.
6. Place a patch over the closed eyelid.

7. Apply tape from the cheek to the middle of the forehead in a diagonal line.

8. Cover the patch with overlapping pieces of tape.

Pressure Eye Patch

1. Assemble the equipment:
 - Two eye patches for each eye requiring treatment
 - Skin preparation pad
 - Nonallergenic paper tape
- 2-5. Follow corresponding steps under Nonpressure Eye Patch.
6. Fold one eye patch in half, place it over the closed eyelid, and apply a second eye patch (unfolded) over the folded one.

- 7, 8. Follow corresponding steps under Nonpressure Eye Patch.

the compresses. Teach him or her to immediately report increasing redness, purulent drainage, or reduced vision to the ophthalmologist.

KERATOCONJUNCTIVITIS SICCA

Pathophysiology

The lacrimal system moistens the eye surface with tears and removes tears from the eye. Problems arise from reduced tear production, infection, or inflammation in the lacrimal system.

Keratoconjunctivitis sicca, or dry eye syndrome, results from changes in tear production, tear composition, or tear distribution. Drugs (e.g., antihistamines, beta-adrenergic blocking agents, anticholinergic drugs) also can reduce tear production. Diseases associated with decreased tear production include rheumatoid arthritis, leukemia, sarcoidosis, and Sjögren's syndrome. Radiation or chemical burns to the eye also decrease tear production. Injury to cranial nerve VII inhibits tears. Eye dryness may follow vision-enhancing surgery. Dry eye syndromes are much more common in women than in men (Pullen & Hall, 2010).

PATIENT-CENTERED COLLABORATIVE CARE

The patient has a foreign body sensation in the eye, burning and itching eyes, and *photophobia* (sensitivity to light). The corneal light reflex is dulled. Tears contain mucus strands.

Management depends on symptom severity. Cyclosporine (Restasis) eyedrops may be prescribed to increase tear production. Artificial tears (HypoTears, Refresh) also can be used to reduce daytime dryness. A lubricating ointment (Lacri-Lube SOP, Refresh P.M.) is used at night. If the dry eye syndrome is caused by an abnormal eyelid position, surgery may be needed.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution is most important for the nurse to teach a client who is prescribed to use an ophthalmic ointment?

- "Keep the tube in the refrigerator to make the ointment easier to control when you squeeze the tube."
- "Wear gloves when you apply the ointment to prevent absorbing the drug through your skin."
- "Patch your eye at night to prevent ointment from getting on your bedding or in your hair."
- "Do not drive with ointment in your eyes."

CONJUNCTIVAL DISORDERS

The conjunctiva is a thin mucous membrane that covers and protects the eye. Because of its location, the conjunctiva is subject to trauma and infection.

Hemorrhage

Conjunctival blood vessels are fragile and can break with increased pressure during sneezing, coughing, or vomiting. Hemorrhages may also occur with hypertension, trauma, or blood clotting problems.

The small, well-defined area of hemorrhage is bright red under the conjunctiva. The patient is usually concerned

about its appearance although no pain or visual impairment occurs with the hemorrhage. It resolves within 14 days without treatment.

Conjunctivitis

Conjunctivitis is an inflammation or infection of the conjunctiva. Inflammation occurs from exposure to allergens or irritants. Infectious conjunctivitis occurs with bacterial or viral infection and is readily transmitted from person to person (Saligan & Yeh, 2008).

Allergic conjunctivitis manifestations are edema, a sensation of burning, a "bloodshot" eye appearance, excessive tears, and itching. Management includes vasoconstrictor and corticosteroid eyedrops (see Chart 49-2). Teach women to avoid using makeup near the eye until all symptoms have subsided.

Bacterial conjunctivitis, or "pink eye," is usually caused by *Staphylococcus aureus* or *Haemophilus influenzae*. Manifestations are blood vessel dilation, mild edema, tears, and discharge. The discharge is watery at first and then becomes thicker, with shreds of mucus.

Cultures of the drainage are obtained to identify the organism. Drug therapy with topical antibiotics is prescribed to eliminate the infection. Nursing interventions focus on preventing infection spread to the other eye or to other people. Document the amount, color, and type of drainage. Remind the patient to wash his or her hands after touching the eye and before using eyedrops. Warn him or her not to touch the unaffected eye without first washing the hands and to avoid sharing washcloths and towels with others. Instruct women to discard eye makeup and applicators used at the time the infection developed to avoid the possibility of recontamination.

Trachoma

Trachoma is a chronic conjunctivitis caused by *Chlamydia trachomatis*. It scars the conjunctiva and is a common cause of preventable blindness worldwide. The incidence is highest in warm, moist climates where sanitation is poor.

The incubation period is 5 to 14 days, and at first the disease resembles bacterial conjunctivitis. Manifestations include tears, photophobia, and eyelid edema. Follicles form on the upper eyelid conjunctiva. As the disease progresses, the eyelid scars and turns inward, causing the eyelashes to damage the cornea.

Cultures are used to identify the causative organism. A 4-week course of oral or topical tetracycline (Achromycin, Apo-Tetra) or erythromycin (Apo-Erythro-EC, E-Mycin, E.E.S.) is given. Azithromycin (Zithromax) can be used once per week for 1 to 3 weeks.

Nursing interventions focus on infection control. Teach the patient to wash the hands before and after touching the eyes. Teach him or her to keep washcloths separate from those of unaffected people and to launder them separately.

NURSING SAFETY PRIORITY

Action Alert

Teach patients who are prescribed antibiotic eyedrops or ointments to complete the entire course of antibiotics. Stopping antibiotic therapy too soon promotes infection recurrence and development of antibiotic-resistant bacteria.

CORNEAL DISORDERS

For a sharp image to be focused on the retina, the cornea must be transparent and intact. Corneal problems may be caused by irritation or infection (keratitis) with ulceration of the corneal surface, degeneration of the cornea (keratoconus), or deposits in the cornea. All corneal problems reduce the refracting power of the cornea, and some can lead to blindness.

CORNEAL ABRASION, ULCERATION, AND INFECTION

Pathophysiology

A **corneal abrasion** is a scrape or scratch of the cornea that disrupts its integrity. This painful condition can be caused by a small foreign body, trauma, or, most commonly, contact lens use. Other conditions that promote loss of corneal integrity include malnutrition, dry eye syndromes, and some cancer therapies. The abrasion allows organisms to enter, leading to corneal infection. Bacterial, protozoal, and fungal infections can lead to **corneal ulceration**, which is a deeper disruption of the epithelium. *This problem is an emergency because the cornea has no separate blood supply and infections that can permanently impair vision develop rapidly.* Use of homemade contact lens solutions and the use of large-volume solution containers that can easily become contaminated have led to a sharp rise in the incidence of corneal ulcers infected with *Pseudomonas aeruginosa* and fungi.

PATIENT-CENTERED COLLABORATIVE CARE

The patient with a corneal disorder has pain, reduced vision, photophobia, and eye secretions. Cloudy or purulent fluid may be present on the eyelids or lashes. Wear gloves when examining the eye.

The entire cornea may look hazy or cloudy with a patchy area of ulceration. When fluorescein stain is used, the patchy areas appear green. Microbial culture and corneal scrapings can help determine the causative organism. Anti-infective therapy is started before the organism is identified because of the high risk for vision loss. For culture, obtain swabs from the ulcer and its edges. For corneal scrapings, the cornea is anesthetized with a topical agent and a physician or advanced practice nurse remove samples from the center and edge of the ulcer.

Antibiotics, antifungals, and antivirals are prescribed to reduce or eliminate the organisms. Usually, a broad-spectrum antibiotic is prescribed first and may be changed when culture results are known. Steroids may be used with antibiotics to reduce the inflammatory response in the eye. Drugs can be given topically as eyedrops, injected subconjunctivally, or injected IV. **Chart 48-4** in **Chapter 48** lists best practices for instilling eyedrops. The nursing priorities are to begin the drug therapy, to ensure patient understanding of the drug therapy regimen, and to prevent infection spread.

Often, the anti-infective therapy involves instilling eyedrops *every hour* for the first 24 hours. Teach the patient how to apply the eyedrops correctly. (See **Chart 48-2** in **Chapter 48**.) Use sterile saline eyedrops to demonstrate the technique,

and obtain a return demonstration. If the patient cannot safely self-apply the drugs, teach a family member how to do it.

If the eye infection occurs from a corneal abrasion or ulcer, only one eye is affected. Teach the patient not to use the drug in the unaffected eye. In addition, teach him or her to wash hands after touching the affected eye and before touching or doing anything to the healthy eye. If both eyes are infected, separate bottles of drugs are needed for each eye. Teach the patient to clearly label the bottles “right eye” and “left eye” and not to switch the drugs from eye to eye. Also teach him or her to completely care for one eye, then wash the hands, and using the drugs for the remaining eye, care for that eye. Teach the patient not to wear contact lenses during the entire time that these drugs are being used because the eye then has fewer protections against infection or injury. In addition, the drugs can cloud or damage the contact lenses.

Stress the importance of applying the drug as often as prescribed, even at night. Stopping the infection at this stage can save the vision in the infected eye. Also instruct the patient to make and keep all follow-up appointments; usually the patient is seen again in 24 hours or less.

The type of anti-infective used and the frequency of application may change when the organism is identified and the infection is responding to the therapy. Drug therapy may continue for 3 or more weeks to ensure eradication of the infection. Warn women to avoid using makeup around the eye until the infection has cleared to prevent spread of infection. Instruct patients to discard all open containers of contact lens solutions and bottles of eyedrops because these may be contaminated. Patients should not wear contact lenses for weeks to months until the infection is gone and the ulcer is healed.

KERATOCONUS AND CORNEAL OPACITIES

Pathophysiology

The cornea can permanently lose its shape, become scarred or cloudy, or become thinner. When these conditions occur, refraction is reduced and images are not focused sufficiently for useful vision. **Keratoconus**, the degeneration of the corneal tissue resulting in abnormal corneal shape, can occur with trauma or may be an inherited disorder (**Fig. 49-2**). Inadequately treated corneal infections and severe trauma

FIG. 49-2 Profile of a normal cornea and one with keratoconus.

FIG. 49-3 The steps involved in corneal transplantation (penetrating keratoplasty).

can damage and scar the cornea and lead to severe visual impairment that can be improved only by surgical interventions.

PATIENT-CENTERED COLLABORATIVE CARE

For a misshaped cornea that is still clear, surgical management involves a corneal implant that adjusts the shape of the cornea. The device approved for this procedure is the Intacs corneal ring. With this procedure, the shape of the cornea is changed by placing a flexible ring in the outer edges of the cornea (outside of the optical zone).

The procedure is performed on both eyes during one surgery under local anesthesia. Improvement to best vision is immediate. Overcorrection or undercorrection of refraction is possible. However, removal, replacement, or adjustment of ring tightness can enhance satisfaction. In addition, replacements can be made if the patient's vision changes further as a result of aging. Because the ring is applied to the cornea outside of the optical zone, the risk for corneal clouding or scarring is lower than with other surgical eye procedures.

Surgery to improve clarity for a permanent corneal disorder that obscures vision is a **keratoplasty** (corneal transplant), in which the diseased corneal tissue is removed and replaced with tissue from a human donor cornea. This process improves vision by removing corneal deformities and replacing them with healthy corneal tissue.

Preoperative care may be short, with little time for teaching because transplantation is performed when the donor cornea becomes available. The patient is usually anxious. Use a calm approach to assess his or her knowledge of the surgery and of care before and after surgery.

Examine the eyes for signs of infection, and report any redness, drainage, or edema to the ophthalmologist. Instill prescribed antibiotic eyedrops, and obtain IV access before surgery.

Operative procedures are *keratoplasties* and are usually performed with local anesthesia in an ambulatory surgical setting. The transplant may involve the entire depth of corneal

FIG. 49-4 The appearance of the eye with sutures in place after corneal transplantation.

tissue (penetrating keratoplasty) or only certain layers of the corneal tissue (lamellar keratoplasty). The nerves around and behind the eye are numbed so that the patient cannot move or see out of the eye. The center 7 to 8 mm of the diseased cornea is removed (Fig. 49-3) with an instrument that works like a cookie cutter. The same instrument is used to cut the tissue graft from the donor cornea so that the graft will be a perfect fit. The donor corneal graft is sutured into place on the eye. Fig. 49-4 shows the eye after transplantation. The procedure usually takes about an hour, and the patient is discharged to home 1 to 2 hours after the procedure.

Postoperative care involves extensive patient teaching. After the procedure, an antibiotic is injected under the conjunctiva and an antibiotic ointment instilled. The eye is covered with a pressure patch and a protective shield until the next day, when the patient returns to the surgeon.

Notify the ophthalmologist of changes in vital signs or of drainage on the dressing. Instruct the patient to lie on the nonoperative side to reduce intraocular pressure (IOP).

TABLE 49-1 ACTIVITIES THAT INCREASE INTRAOCULAR PRESSURE

- | | |
|---|--|
| • Bending from the waist | • Vomiting |
| • Lifting objects weighing more than 10 lbs | • Having sexual intercourse |
| • Sneezing, coughing | • Keeping the head in a dependent position |
| • Blowing the nose | • Wearing tight shirt collars |
| • Straining to have a bowel movement | |

Show the patient or family member how to apply a patch, and obtain a return demonstration. The patch may need to be worn during the day for the first 3 to 5 days. Teach the patient to wear the shield at night for the first month after surgery and whenever he or she is around small children or pets. Instruct him or her *not* to use an ice pack on the eye. Complications after surgery include bleeding, wound leakage, infection, and graft rejection. Teach the patient how to instill eyedrops, and obtain a return demonstration. Show pictures of what the eye and sutures should look like. Teach him or her to examine the eye (or have a family member do the examination) daily for the presence of infection or graft rejection. The presence of purulent discharge, a continuous leak of clear fluid from around the graft site (not tears), or excessive bleeding should be reported immediately to the surgeon. Other complications include decreased vision, increased redness of the eye, pain, increased sensitivity to light, and the presence of light flashes or “floaters” in the field of vision. Teach the patient to report any of these manifestations to the surgeon if they develop after the first 48 hours and persist for more than 6 hours.

The eye should be protected from any activity that can increase the pressure on, around, or inside the eye. Teach the patient to avoid jogging, running, dancing, and any other activity that promotes rapid or jerky head motions for several weeks after surgery. Other activities that may raise intraocular pressure (IOP) and should be avoided are listed in Table 49-1. Returning to work depends on the type of work. Patients who have sedentary jobs, such as secretaries, may return to work in 1 week, whereas those who perform heavy lifting or manual labor may need to be off work for 6 to 8 weeks.

Graft rejection can occur. Inflammation starts in the donor cornea near the graft edge and moves toward the center. Vision is reduced, and the cornea becomes cloudy. Topical corticosteroids and other immunosuppressants are used to stop the rejection process. If rejection continues, the graft becomes opaque and blood vessels branch into the opaque tissue.

Eye donation is a common procedure and needed for corneal transplantation. Corneal tissue is obtained from a local eye or tissue bank. An eye bank obtains its supply of corneal tissue from volunteer donors. These donors must be free of infectious disease or cancer at the time of death. If a deceased patient is a potential eye donor, follow these steps:

- Raise the head of the bed 30 degrees.
- Instill prescribed antibiotic eyedrops, such as Neosporin or tobramycin.
- Close the eyes, and apply a *small* ice pack to the closed eyes.
- Contact the family and physician to discuss eye donation.

**FIG. 49-5** The visual impairment produced by the presence of a cataract.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which comment made by a client 1 week after a corneal transplant indicates to the nurse a need to review postoperative care?

- A. “I have been feeding my cat on the counter so that I don’t have to bend over.”
- B. “I have been using an icepack on my eye to reduce the redness and swelling.”
- C. “My daughter has been helping me inspect my eye and place the eyedrops.”
- D. “Instead of reading a book, I now listen to books on tape.”

CATARACT

Pathophysiology

The lens is a transparent, refractive elastic structure suspended behind the iris. A **cataract** is a lens opacity that distorts the image projected onto the retina (Fig. 49-5). With aging, the lens gradually loses water and increases in density (Touhy & Jett, 2010). This increased density occurs as older lens fibers are compressed and new fibers are produced in the outer layers. Lens proteins dry out and form crystals. As the density of the lens increases, it becomes opaque with a painless loss of transparency. Both eyes may have cataracts; however, the rate of progression in each eye is usually different.

Etiology and Genetic Risk

Cataracts are classified by nature or by onset. They may be present at birth or develop at any time. Cataracts may be age-related or caused by trauma or exposure to toxic agents. They also occur with other diseases and eye disorders (Table 49-2).

Incidence/Prevalence

About 20 to 22 million people in North America have cataracts (National Eye Institute, 2010; Statistics Canada, 2010). The age-related cataract is the most common type. Some degree of cataract formation is expected in all people older than 70 years.

TABLE 49-2 COMMON CAUSES OF CATARACTS**Age-Related Cataracts**

- Lens water loss and fiber compaction

Traumatic Cataracts

- Blunt injury to eye or head
- Penetrating eye injury
- Intraocular foreign bodies
- Radiation exposure, therapy

Toxic Cataracts

- Corticosteroids
- Phenothiazine derivatives
- Miotic agents

Associated Cataracts

- Diabetes mellitus
- Hypoparathyroidism
- Down syndrome
- Chronic sunlight exposure

Complicated Cataracts

- Retinitis pigmentosa
- Glaucoma
- Retinal detachment

**FIG. 49-6** The appearance of an eye with a mature cataract.

Health Promotion and Maintenance

Although most cases of cataracts in North America are age-related, the onset of cataract formation occurs earlier with heavy sun exposure or exposure to other sources of ultraviolet (UV) light. Teach people to reduce the risk for cataract by wearing sunglasses that limit exposure to UV light whenever they are out in bright sunlight. Cataracts also may result from direct eye injury. Urge all people to wear eye and head protection during sports, such as baseball, or any activity that increases the risk for the eye being hit by objects in motion.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Age is important because cataracts are most prevalent in the older adult. Ask about these predisposing factors:

- Recent or past trauma to the eye
- Exposure to radioactive materials, x-rays, or UV light
- Systemic disease (e.g., diabetes mellitus, hypoparathyroidism, Down syndrome)
- Prolonged use of corticosteroids, chlorpromazine, beta blockers, or miotic drugs
- Intraocular disease (e.g., recurrent uveitis)

Ask the patient to describe his or her vision. For example, you might say, “Tell me what you can see well and what you have difficulty seeing.”

Physical Assessment/Clinical Manifestations

Early manifestations of cataracts are slightly blurred vision and decreased color perception. At first, the patient may think his or her glasses or contact lenses are smudged. As lens cloudiness continues, blurred and double vision occur and

the patient may have difficulty with ADLs. Without surgical intervention, visual impairment progresses to blindness. *No pain or eye redness is associated with age-related cataract formation.*

Vision is tested using a Snellen chart and brightness acuity testing (see [Chapter 48](#)). Examine the lens with an ophthalmoscope, and describe any observed densities by size, shape, and location. As the cataract matures, the opacity makes it difficult to see the retina and the red reflex may be absent. When this occurs, the pupil is white ([Fig. 49-6](#)).

Psychosocial Assessment

Loss of vision is gradual, and the patient may not be aware of it until reading or driving is affected. Fear of blindness can be overwhelming, and the patient has anxiety about loss of independence. Encourage the patient and family to express concerns about reduced vision.

PLANNING AND IMPLEMENTATION

The priority problem for the patient with cataracts is reduced vision, which is a safety risk. Patients often live with reduced vision for years before the cataract is removed. Interventions for safety and independence before surgery are on pp. 1073-1075 in Patient-Centered Collaborative Care in the Reduced Vision section.

Improving Vision

Planning: Expected Outcomes. The patient with cataracts is expected to recognize when he or she is no longer able to perform ADLs safely and independently and then is expected to have cataract surgery. This procedure is covered by Medicare for patients who are 65 years or older.

Interventions. Surgery is the only “cure” for cataracts. After vision is reduced to the extent that ADLs are affected, the surgery should be performed as soon as possible.

Preoperative Care. The health care provider has the responsibility of (1) giving the patient accurate information so that he or she can make informed decisions about treatment and (2) obtaining informed consent. Reinforce this information, and teach about the nature of cataracts, their progression, and their treatment.

Because cataract surgery is usually an ambulatory procedure and most patients are older, preoperative teaching is challenging. Assess how the patient’s vision affects ADLs, especially dressing, eating, and ambulating. Stress that care

FIG. 49-7 Cataract removal by phacoemulsification.

after surgery requires the instillation of different types of eyedrops several times a day for 2 to 4 weeks. Careful assessment of eye appearance is also needed. If the patient is unable to perform these tasks, help him or her make arrangements for this care.

Ask the patient whether he or she takes any drugs that affect blood clotting, such as aspirin, warfarin (Coumadin), clopidogrel (Plavix), and dabigatran (Pradaxa). Ensure that this information is communicated to the surgeon because some of these drugs may need to be discontinued before cataract surgery.

An IV infusion may or may not be started in the operating room. A sedative is given before surgery, and a series of ophthalmic drugs are instilled just before surgery to dilate the pupils and cause vasoconstriction. Other eyedrops are instilled to induce paralysis to prevent lens movement. When the patient is in the surgical area, a local anesthetic is injected into the muscle cone behind the eye for anesthesia and eye paralysis.

Operative Procedures. Extraction of the lens is most commonly performed by *phacoemulsification* (Fig. 49-7). A probe is inserted through the capsule, and high-frequency sound waves break the lens into small pieces, which are then removed by suction. The capsule remains intact, and the replacement intraocular lens (IOL) is placed inside it to focus light rays in the retina. The IOL is a small, clear, plastic lens. Different types are available, and one is selected by the surgeon and patient to allow correction of a specific refractive error. Some patients have distant vision restored to 20/20 and may need glasses only for reading or close work. Some replacement lenses have multiple focal planes and may correct all vision for a patient to the extent that glasses or contact lenses may not be needed. Lens replacement surgery is now performed for people who do not have cataracts but who want corrected vision.

Postoperative Care. Immediately after surgery, antibiotics are given subconjunctivally. Usually antibiotic and steroid

ointments also are instilled. The eye is left unpatched, and the patient is discharged within an hour after surgery. Instruct him or her to wear dark glasses outdoors or in brightly lit environments until the pupil responds to light. Teach the patient and family members how to instill the prescribed eyedrops. (See Chart 48-2 in Chapter 48.) Work with them in creating a written schedule for the timing and the order of eyedrops administration. Stress the importance of keeping all follow-up appointments.

Remind the patient that mild eye itching is normal, as is a “bloodshot appearance.” The eyelid may be slightly swollen. However, significant swelling or bruising is abnormal. Cool compresses may be beneficial. Discomfort at the site is controlled by a mild analgesic such as acetaminophen (Abenol , Tylenol) or acetaminophen with oxycodone (Endocet , Percocet, Tylox). Remind him or her to avoid aspirin because of its effects on blood clotting.

Pain early after surgery may indicate increased intraocular pressure (IOP) or hemorrhage. Teach patients to contact the surgeon if pain occurs with nausea or vomiting.

To reduce increases in IOP, teach the patient and family about activity restrictions. Activities that can cause a sudden rise in IOP are listed in Table 49-1.

Another major complication is infection. Teach the patient and family to observe for increasing redness of the eye, a change in visual acuity, tears, and photophobia. Creamy white, dry, crusty drainage on the eyelids and lashes is normal. However, yellow or green drainage indicates infection and must be reported.

Patients experience a dramatic improvement in vision on the day of surgery. Remind them that final best vision will not be present until 4 to 6 weeks after surgery. However, vision is not expected to become worse after the procedure.

NURSING SAFETY PRIORITY

Action Alert

Instruct the patient who has had cataract surgery to immediately report any reduction of vision after surgery in the eye that had the cataract removed.

Community-Based Care

The patient is usually discharged within an hour after cataract surgery. Nursing interventions focus on helping the patient and family with plans for return to the home, assisted-living, or extended-care setting.

Home Care Management

If the patient has difficulty instilling eyedrops, a supportive neighbor, friend, or family member can be taught the procedure. Adaptive equipment that positions the bottle of eyedrops directly over the eye can also be purchased (Fig. 49-8). Eyedrops are often prescribed for 2 to 6 weeks after cataract surgery.

Teaching for Self-Management

The best outcome of cataract removal requires close adherence to the drug regimen after surgery. Providing the patient or family with accurate information and demonstration of needed skills are nursing priorities for this patient population (Lockey, 2009). Review these indications of complications

FIG. 49-8 The Xal-Ease adaptive device for self-administering eyedrops.

after cataract surgery with the patient and family before discharge:

- Sharp, sudden pain in the eye
- Bleeding or increased discharge
- Green or yellow, thick drainage
- Lid swelling
- Reappearance of a bloodshot sclera after the initial appearance has cleared
- Decreased vision
- Flashes of light or floating shapes

Remind the patient to avoid activities that might increase IOP (see [Table 49-1](#)). Hair may be washed a day or two after surgery but only with the head tilted back, such as in a beauty salon or barber shop, to avoid getting water in the eye. Teach the patient to stand in the shower with the face away from the showerhead for the first week after surgery.

Teach the patient about activity restrictions. Cooking and light housekeeping are permitted, but vacuuming should be avoided for several weeks because of the forward flexion involved and the rapid, jerky movements required. Advise him or her to refrain from driving, operating machinery, and participating in sports until given specific permission from the ophthalmologist. [Chart 49-5](#) lists items to cover in the focused assessment of a patient in the home environment after cataract surgery.

Health Care Resources

If the patient lives alone and has no support, arrange for a home care nurse to assess him or her and the home situation. If the patient is unable to instill eyedrops independently, a friend, neighbor, or family member can be taught this technique.

EVALUATION: OUTCOMES

Evaluate the care of the patient with cataracts on the basis of improving vision. The expected outcomes include that the patient after cataract surgery will:

CHART 49-5 HOME CARE ASSESSMENT

The Patient after Cataract Surgery

Assess the eye and vision:

- Visual acuity in both eyes using a Jaeger card
- Visual fields of both eyes
- Compare operative eye with nonoperative eye for presence or absence of:
 - Redness
 - Tearing
 - Drainage

Ask the patient about:

- Pain in or around the operative eye
- Any change in visual acuity (decreased or improved) in the operative eye
- Whether any of these has been noticed in the operative eye:
 - Dark spots
 - Increase in the number of floaters
 - Bright flashes of light

Assess the home environment for:

- Safety hazards (especially tripping and falling hazards)
- Kitchen hazards
- Level of room lighting

Assess patient adherence with and understanding of treatment and limitations, such as:

- Signs and symptoms to report
- Drug regimen
- Activity restrictions

Assess functional ability:

- Activities of daily living
- Adherence to drug regimen

- Have improved sensory function (vision)
- Recognize manifestations of complications

Specific indicators for these outcomes are listed under the Planning and Implementation section (see earlier).

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client who had cataract removal with placement of an intraocular implant 1 week ago now calls in and reports that her eye is more bloodshot than it was yesterday and that a small amount of greenish drainage is present. What is the priority nursing action?

- Reassure the client that these symptoms are normal for this stage of recovery after cataract surgery.
- Explain how to apply a wet compress to the affected eye for 15 minutes four times daily.
- Instruct the client to come to the office immediately to be seen by the ophthalmologist.
- Instruct the client to use the antibiotic eyedrops four times daily instead of twice daily.

GLAUCOMA

Pathophysiology

Glaucoma is a group of eye disorders resulting in increased IOP. Intraocular pressure (IOP) is the fluid pressure within the eye. As described in [Chapter 48](#), the eye is a hollow organ. For proper eye function, the gel in the posterior segment (vitreous humor) and the fluid in the anterior segment (aqueous humor) must be present in set amounts that apply pressure inside the eye to keep it ball-shaped.

TABLE 49-3 COMMON CAUSES OF GLAUCOMA**Primary Glaucoma**

- Aging
- Heredity
- Central retinal vein occlusion

Associated Glaucoma

- Diabetes mellitus
- Hypertension
- Severe myopia
- Retinal detachment

Secondary Glaucoma

- Uveitis
- Iritis
- Neovascular disorders
- Trauma
- Ocular tumors
- Degenerative disease
- Eye surgery

The gel-like vitreous humor is made as the eyes form and grow. Once eye growth is complete, this volume does not change. The aqueous humor, however, is continuously made from blood plasma. The ciliary bodies located behind the iris and just in front of the lens make and secrete this fluid (see Fig. 48-2 in Chapter 48). The fluid flows through the pupil into the bulging area in front of the iris. At the outer edges of the iris beneath the cornea, blood vessels collect fluid and return it to the blood. Usually about 1 mL of aqueous humor is present at all times, but it is continuously made and reabsorbed at a rate of about 5 mL daily. *A normal IOP requires a balance between production and outflow of aqueous humor. If the IOP becomes too high, the extra pressure compresses retinal blood vessels and photoreceptors and their synapsing nerve fibers. This compression results in poorly oxygenated photoreceptors and nerve fibers. These sensitive nerve tissues become ischemic and die. When too many have died, sight is lost and the person is permanently blind.* Tissue damage usually starts in the periphery and moves inward toward the fovea centralis. Left untreated, glaucoma can result in blindness. Glaucoma is usually painless, and the patient may be unaware of a gradual reduction in vision.

There are several causes and types of glaucoma (Table 49-3). It is classified as primary, secondary, or associated. In primary glaucoma, the most common form, the structures involved in circulation and reabsorption of the aqueous humor undergo direct pathologic change.

Primary open-angle glaucoma (POAG), the most common form of primary glaucoma, usually affects both eyes and has no symptoms in the early stages. Outflow of aqueous humor through the chamber angle is reduced. Because the fluid cannot leave the eye at the same rate it is produced, IOP gradually increases. **Primary angle-closure glaucoma** (also called *PACG* or *acute glaucoma*) is less common, has a sudden onset, and is an emergency. The basic problems are a narrowed angle and forward displacement of the iris. The iris pressing against the cornea closes the chamber angle, obstructing the outflow of aqueous humor. This can happen suddenly and without warning. It is more common in women and Asian patients (Kock & Sikes, 2009).

Glaucoma is a common cause of blindness in affluent countries. It is age-related, occurring in about 10% of people older than 80 years (McCance et al., 2010).

PATIENT-CENTERED COLLABORATIVE CARE

Primary open-angle glaucoma (POAG) develops slowly, with gradual loss of visual fields that may go unnoticed because central vision is unaffected. At times, the patient may have foggy vision, reduced accommodation, mild aching in the eyes, or headaches and may require frequent changes in eye-glass prescriptions. Late manifestations occur after irreversible damage to optic nerve function and include seeing halos around lights, losing peripheral vision, and having decreased vision that does not improve with eyeglasses. The Concept Map on p. 1066 addresses collaborative care issues for patients who have glaucoma.

ASSESSMENT

Physical Assessment/Clinical Manifestations

Ophthalmoscopic examination of the patient with glaucoma shows cupping and atrophy of the optic disc. It becomes wider and deeper and turns white or gray. Visual fields are measured to determine the extent of peripheral vision loss. In POAG, the visual fields first show a small defect that gradually progresses to a larger field defect.

Manifestations of acute angle-closure glaucoma differ from those of POAG. The onset is acute, and the patient has sudden, severe pain around the eyes that radiates over the face. Headache or brow pain, nausea, and vomiting may occur. Other manifestations include seeing colored halos around lights and sudden blurred vision with decreased light perception. The sclera may appear reddened and the cornea foggy. Ophthalmoscopic examination reveals a shallow anterior chamber, cloudy aqueous humor, and a moderately dilated, nonreactive pupil.

Diagnostic Assessment

An elevated intraocular pressure (IOP) is measured by tonometry. In open-angle glaucoma, the tonometry reading is between 22 and 32 mm Hg (normal is 10 to 21 mm Hg). In angle-closure glaucoma, the tonometry reading may be 30 mm Hg or higher. Visual field testing by perimetry is performed, as is visualization by gonioscopy to determine whether the angle is open or closed (Sharts-Hopko & Glynn-Milley, 2009). Usually, the optic nerve is imaged to determine to what degree nerve damage is present. All of these diagnostic assessment techniques are described in Chapter 48.

INTERVENTIONS

Nonsurgical Management

Blindness from glaucoma can be prevented by early detection, lifelong treatment, and close monitoring with follow-up care. Some degree of vision loss occurs, although use of topical agents that reduce IOP has been found to delay or prevent damage. Chart 49-6 lists ways to assist the person with impaired vision to remain as independent as possible.

Concept Map: Primary Open-Angle Glaucoma (POAG)

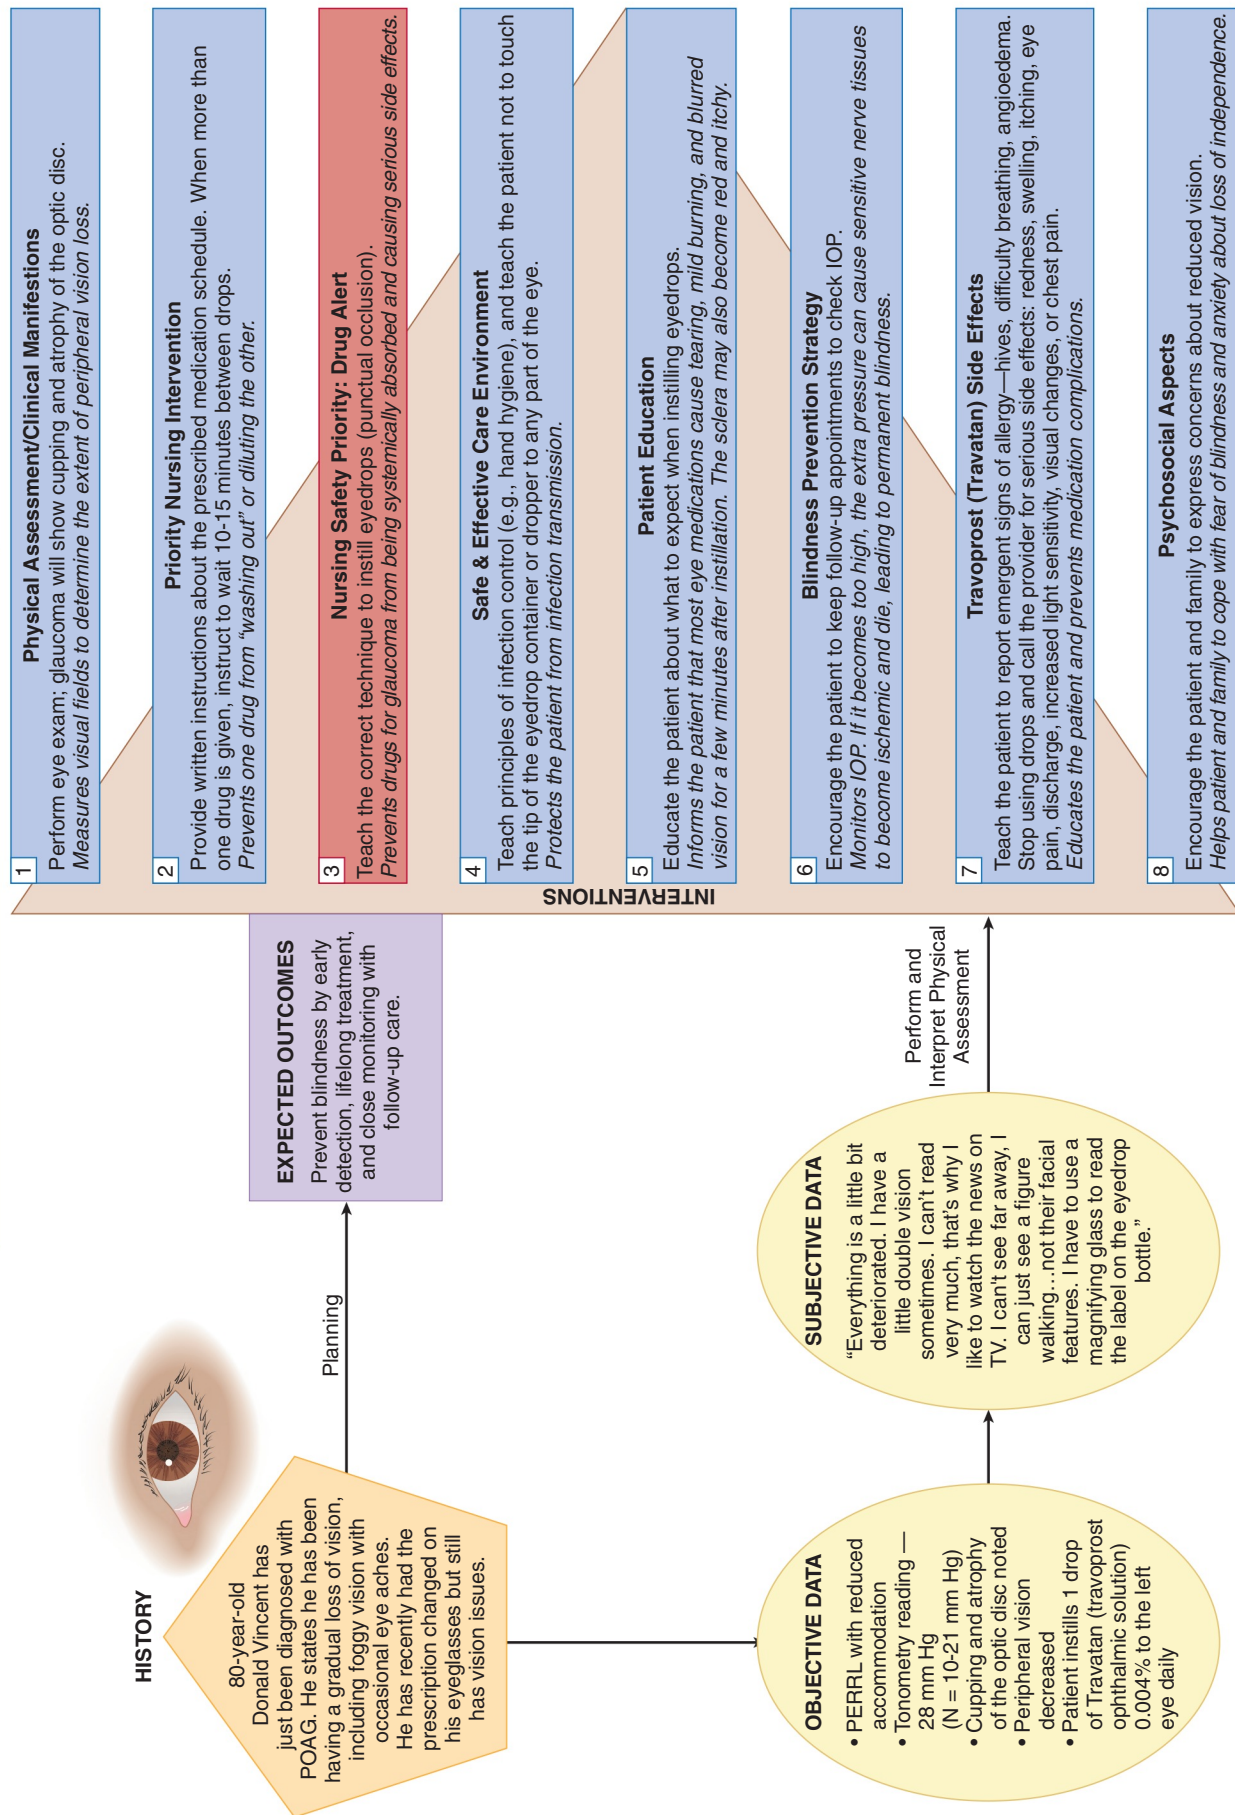

CHART 49-6 NURSING FOCUS ON THE OLDER ADULT

Promote Independent Living in Patients with Impaired Vision**Drugs**

- Having a neighbor, relative, friend, or visiting nurse visit once a week to measure the proper drugs for each day may be helpful.
- If the patient is to take drugs more than once each day, it is helpful to use a container of a different shape (with a lid) each time. For example, if the patient is to take drugs at 9 AM, 1 PM, and 9 PM, the 9 AM drugs would be placed in a round container, the 1 PM drugs in a square container, and the 9 PM drugs in a triangular container.
- It is helpful to place each day's drug containers in a separate box with raised letters on the side of the box spelling out the day.
- "Talking clocks" are available for the patient with low vision.
- Some drug boxes have alarms that can be set for different times.

Communication

- Telephones with large, raised block numbers may be helpful. The best models are those with black numbers on a white phone or white numbers on a black phone.
- Telephones that have a programmable, automatic dialing feature are very helpful. Programmed numbers should include those for the fire department, police, relatives, friends, neighbors, and 911.

Safety

- It is best to leave furniture the way the patient wants it and not move it.
- Throw rugs are best eliminated.
- Appliance cords should be short and kept out of walkways.
- Lounge-style chairs with built-in footrests are preferable to footstools.
- Nonbreakable dishes, cups, and glasses are preferable to breakable ones.
- Cleansers and other toxic agents should be labeled with large, raised letters.
- Hook-and-loop (Velcro) strips at hand level may help mark the locations of switches and electrical outlets.

Food Preparation

- Meals on Wheels is a service that many older adults find helpful. This service brings meals at mealtime, cooked and ready to eat.

The cost of this service varies, depending on the patient's ability to pay.

- Many grocery stores offer a "shop by telephone" service. The patient can either complete a computer booklet indicating types, amounts, and brands of items desired, or the store will complete this booklet over the telephone by asking the patient specific information. The store then delivers groceries to the patient's door (many stores also offer a "put away" service) and charges the patient's bank card.
- A microwave oven is a safer means of cooking than a standard stove, although many older patients are afraid of microwave ovens. If the patient has and will use a microwave oven, others can prepare meals ahead of time, label them, and freeze them for later use. Also, many microwavable complete frozen dinners that comply with a variety of dietary restrictions are available.
- Friends or relatives may be able to help with food preparation. Often relatives do not know what to give an older person for birthdays or other gift-giving occasions. One suggestion is a homemade prepackaged frozen dinner that the patient enjoys.

Personal Care

- Handgrips should be installed in bathrooms.
- The tub floor should have a nonskid surface.
- Male patients should use an electric shaver rather than a razor.
- Choosing a hairstyle that is becoming but easy to care for (avoiding parts) helps in independent living.
- Home hair care services may be available.

Diversional Activity

- Some patients can read large-print books, newspapers, and magazines (available through local libraries and vision services).
- Books, magazines, and some newspapers are available on audiotapes or discs.
- Patients experienced in knitting or crocheting may be able to create items fashioned from straight pieces, such as afghans.
- Card games, dominoes, and some board games that are available in large, high-contrast print may be helpful for patients with low vision.

Drug therapy for glaucoma focuses on reducing IOP through these mechanisms:

- Constricting the pupil so that the ciliary muscle is contracted, allowing better circulation of the aqueous humor to the site of absorption
- Reducing the production or increasing the absorption of aqueous humor

Eyedrop drugs are the mainstay of control for glaucoma. They do not improve lost vision but prevent more damage by decreasing IOP. The classes of drugs to manage glaucoma are the prostaglandins agonists, adrenergic agonists, beta-adrenergic blockers, cholinergic agonists, and carbonic anhydrase inhibitors. Most eyedrops cause tearing, mild burning, and blurred vision for a few minutes after instilling the drug. The sclera may also become red and itchy. Specific drug actions and nursing interventions are listed in [Chart 49-7](#).

The priority nursing intervention for the patient on drug therapy for glaucoma is teaching. Provide written instructions similar to those in [Chart 48-2](#) in [Chapter 48](#). The benefit of drug therapy is achieved only when the drugs are used on the prescribed schedule, usually every 12 hours. Teach patients

the importance of instilling the drops on time and not skipping doses. When more than one drug is prescribed, teach him or her to wait 10 to 15 minutes between drug instillations to prevent one drug from "washing out" or diluting another drug. Stress the need for good handwashing, keeping the eyedrop container tip clean, and avoiding touching the tip to any part of the eye. Also teach the technique of punctal occlusion (placing pressure on the corner of the eye near the nose) immediately after eyedrop instillation to prevent systemic absorption of the drug. [Fig. 49-9](#) demonstrates this technique.

! NURSING SAFETY PRIORITY**Drug Alert**

Most eyedrops used for glaucoma therapy can be absorbed systemically and cause serious systemic problems. Although punctal occlusion should be used after instilling any type of eyedrop, it is critical to teach patients to use the technique with eyedrops for glaucoma.

Systemic osmotic drugs may be given for angle-closure glaucoma as part of emergency management to rapidly

CHART 49-7 COMMON EXAMPLES OF DRUG THERAPY (EYEDROPS)

Categories for Management of Glaucoma

CATEGORY AND DRUG	PURPOSE/ACTIONS	NURSING IMPLICATIONS	RATIONALES
Prostaglandin Agonists Bimatoprost (Lumigan) Latanoprost (Xalatan) Travoprost (Travatan)	Drugs lower IOP by dilating the blood vessels in the trabecular mesh of the eye, where the aqueous humor is reabsorbed, collecting more aqueous humor and allowing more fluid to leave the eye.	Teach the patient to check the cornea for abrasions or other signs of trauma. Remind the patient that, over time, the eye color darkens and eyelashes elongate in the eye receiving the drug. If only one eye is to be treated, teach the patient <i>not</i> to place drops in the other eye to try to make the eye colors similar. Warn the patient that using higher doses than are prescribed can reduce the effectiveness of the drug in controlling the glaucoma.	Drugs should not be used when the cornea is not intact. Knowing the side effects in advance reassures the patient that their presence is expected and normal. Using the drug in an eye with normal IOP can cause a <i>lower</i> -than-normal IOP, which reduces vision. Drug action is based on blocking receptors, which can increase in number when the drug is overused.
Adrenergic Agonists Apraclonidine (Iopidine) Brimonidine tartrate (Alphagan) Dipivefrin hydrochloride (Propine)	These drugs bind to receptors in the eye, reducing the amount of aqueous humor produced by the ciliary bodies. In addition, the pupil of the eye is dilated and flow of the fluid through the pupil is improved. Both these actions reduce the amount of fluid present in the eye at any one time, lowering the intraocular pressure.	Ask whether the patient is taking any antidepressants from the MAO inhibitor class, such as phenelzine (Nardil) or tranylcypromine (Parnate). Teach the patient to wear dark glasses outdoors and also indoors when lighting is bright. Teach the patient not to use the eyedrops with contact lenses in place and to wait 15 minutes after using the drug to put in the lenses.	These enzyme inhibitors increase blood pressure as do the adrenergic agonists. When taken together, the patient may experience hypertensive crisis. The pupil dilates (mydriasis) and remains dilated, even when there is plenty of light, causing discomfort. These drugs are absorbed by the contact lens, which can become discolored or cloudy.
Beta-Adrenergic Blockers Betaxolol hydrochloride (Betoptic) Carteolol (Cartrol, Ocupress) Levobunolol (Betagan) Timolol (Betimol, Istalol, Timoptic) Timoptic GFS (gel-forming solution) (Timoptic-XE, Timolol-GFS)	By selectively blocking beta-adrenergic receptors in the eye, less aqueous humor is produced by the ciliary bodies. The fluid also appears to be absorbed slightly faster as a result of this drug therapy. Both actions reduce IOP.	Ask whether the patient has moderate to severe asthma or COPD. Warn diabetic patients to check their blood glucose levels more often when taking these drugs. Teach patients who also take oral beta blockers to check their pulse at least twice per day and to notify the health care provider if the pulse is consistently below 58 beats per minute.	If these drugs are absorbed systemically, they constrict pulmonary smooth muscle and narrow airways. These drugs induce hypoglycemia and also mask the hypoglycemic symptoms. These drugs potentiate the effects of systemic beta blockers and can cause an unsafe drop in heart rate and blood pressure.
Cholinergic Agonists Carbachol (Carboptic, Isopto Carbachol, Miostat) Echothiophate (Phospholine Iodide) Pilocarpine (Adorbocarpine, Akarpine, Isopto Carpine, Ocu-Carpine, Ocusert, Piloptic, PiloSTAT)	These drugs lower IOP by decreasing the amount of aqueous humor produced and by improving flow of the fluid. They make the pupil smaller (miosis) but, at the same time, make more room between the iris and the lens, allowing the fluid to flow through the pupil better even though it is smaller.	Teach the patient not to use more eyedrops than are prescribed and to report increased salivation or drooling to the health care provider. Teach the patient to use good light when reading and to take care in darker rooms.	These drugs are readily absorbed by conjunctival mucous membranes and can cause systemic side effects of headache, flushing, increased saliva, and sweating. The pupil of the eye will not open more to let in more light, and it may be harder to see objects in dim light. This problem can increase the risk for falls.

COPD, Chronic obstructive pulmonary disease; IOP, intraocular pressure; MAO, monamine oxidase.

CHART 49-7 COMMON EXAMPLES OF DRUG THERAPY (EYEDROPS)

Categories for Management of Glaucoma—cont'd

CATEGORY AND DRUG	PURPOSE/ACTIONS	NURSING IMPLICATIONS	RATIONALES
Carbonic Anhydrase Inhibitors			
Brinzolamide (Azopt) Dorzolamide (Trusopt)	Drugs reduce IOP by directly inhibiting production of aqueous humor from the zonules of the ciliary bodies. They do not affect the flow or absorption of the fluid.	Ask whether the patient has an allergy to sulfonamide antibacterial drugs. Teach the patient to shake the drug before applying. Teach the patient not to use the eyedrops with contact lenses in place and to wait 15 minutes after using the drug to put in the lenses.	Drugs are similar to the sulfonamides, and if a patient is allergic to the sulfonamides, an allergy is likely with these drugs, even as eyedrops. Drug separates on standing. These drugs are absorbed by the contact lens, which can become discolored or cloudy.
Combination Drugs			
Brimonidine tartrate and timolol maleate (Combigan)	Same as for each drug alone.	Same as for each drug alone.	Same as for each drug alone.

FIG. 49-9 Applying punctal occlusion to prevent systemic absorption of eyedrops.

reduce IOP. These agents include oral glycerin and IV mannitol (Osmitrol).

Surgical Management

Surgery is used when drugs for the patient with open-angle glaucoma are not effective at controlling IOP. Two common procedures are laser trabeculoplasty and filtering microsurgery. A *laser trabeculoplasty* burns the trabecular meshwork, scarring it and causing the meshwork fibers to tighten. Tight fibers increase the size of the spaces between the fibers, improving outflow of aqueous humor and reducing IOP. *Filtering microsurgery* creates a drainage hole in the iris between the posterior and anterior chambers. Both are ambulatory surgery procedures.

If glaucoma fails to respond to common approaches or if the drainage hole does not remain open, other more invasive procedures may be used. These include deep sclerectomy, viscocanalostomy, or an implanted shunt (Sharts-Hopko & Glynn-Milley, 2009).

A *sclerectomy* for glaucoma involves removing a section of sclera and trabecular meshwork along with a section of the canal of Schlemm to allow more direct drainage of aqueous humor. A *viscocanalostomy* requires removal of a section of

sclera but the main focus is artificially widening the canal of Schlemm to improve drainage. The *implanted shunt* has a small tube or filament connected to a flat plate positioned on the outside of the eye in the eye orbit. (The plate is not visible on the front part of the eye.) The open part of the fine tube is placed into the front chamber of the eye, just in front of the iris. The fluid then drains through the tube (or along the outside of the tube) into the area around the flat plate where it collects and is reabsorbed into the bloodstream.

A serious complication after glaucoma surgery is choroidal hemorrhage. If IOP is too low, fluid may enter the suprachoroid space and cause a choroidal detachment. Extra fluid in this space may break blood vessels located there. Manifestations of choroidal hemorrhage include:

- Acute pain deep in the eye
- Decreased vision
- Vital sign changes

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which assessment question is most important for the nurse to ask a client with glaucoma who has just been prescribed the drug apraclonidine (Iopidine)?

- "Are you allergic to sulfa drugs?"
- "What other drugs do you currently take?"
- "Do you have any difficulty passing urine?"
- "Do you have asthma or any other respiratory problem?"

VITREOUS HEMORRHAGE

The vitreous is the gel that fills the posterior two thirds of the eye and maintains the eye's shape. Vitreous hemorrhage (bleeding into the vitreous cavity) may result from aging, systemic diseases, or trauma. With aging, the vitreous may spontaneously detach from the retina. Torn blood vessels allow bleeding into the vitreous. Diabetes and hypertension damage retinal blood vessels and cause vitreal hemorrhage.

Reduced visual acuity is the main manifestation of vitreous hemorrhage. A mild hemorrhage may cause the patient to see a red haze or "floaters." A moderate hemorrhage may

cause the patient to see “black streaks” or “tiny black dots.” Severe hemorrhage may reduce visual acuity to hand motion. The eye has a reduced red reflex because light rays do not reach the retina. The location and extent of the hemorrhage are determined by ultrasonography.

The hemorrhage may absorb slowly with no treatment. Leaking blood vessels can be sealed with laser therapy. If the hemorrhage is still present several weeks to months later, a **vitrectomy** (surgical removal of the vitreous) may be needed.

UVEITIS

The eye’s uveal tract has three related parts: the iris, the ciliary body, and the choroid. Any of these anterior or posterior structures can become inflamed (**uveitis**).

Anterior uveitis is inflammation of the iris or of the ciliary body, or both. The cause is unknown but uveitis often follows exposure to allergens, infectious agents, trauma, or systemic disease (rheumatoid arthritis, herpes simplex, herpes zoster). It can follow any local or systemic bacterial infection. Manifestations include aching around the eye; tearing; blurred vision; photophobia; a small, irregular, nonreactive pupil; and a “bloodshot” appearance of the sclera.

Posterior uveitis is another term for **retinitis** (inflammation of the retina) and **chorioretinitis** (inflammation of the choroid and the retina). It occurs with tuberculosis, syphilis, and toxoplasmosis.

The onset of symptoms is slow and painless. Reduced vision in the affected eye results from fluid, fibrin, and cells leaking into the vitreous cavity. The pupil is small, nonreactive, and irregularly shaped. Black dots are visible against the red background of the fundus. Lesions appear as grayish yellow patches on the retinal surface.

Management of uveitis includes resting the ciliary body with a cycloplegic drug to paralyze the ciliary muscles and dilate the pupil. This action prevents adhesions from forming between the iris and the lens. Steroid drops are given hourly to reduce the inflammation and to prevent adhesion of the iris to the cornea and lens. Ocular injections of steroids are used in posterior uveitis or when topical steroids have been ineffective. Analgesics that contain neither aspirin nor opioids are prescribed for pain. Systemic antibiotic therapy may be started for posterior uveitis or when infection is present with anterior uveitis.

Cool or warm compresses are applied for ocular pain. Darkening the room and wearing sunglasses reduce the discomfort of photophobia. Because of blurred vision from the cycloplegic drops, instruct the patient not to drive or operate machinery. Review the manifestations of bacterial and fungal ulcers and those of increased intraocular pressure (IOP).

RETINAL DISORDERS

MACULAR DEGENERATION

Pathophysiology

Macular degeneration is the deterioration of the macula (the area of central vision) and can be age-related or exudative. Age-related macular degeneration (AMD) has two types. The most common type is *dry* AMD, caused by gradual blockage of retinal capillaries, allowing retinal cells in the macula to

become ischemic and necrotic. Rod and cone photoreceptors die. Central vision declines, and patients describe mild blurring and distortion at first. Eventually, the person loses all central vision (National Eye Institute, 2010). About 2 million older adults in the United States and Canada have dry AMD (National Eye Institute, 2010; **Statistics Canada, 2010**). This vision loss affects independence, well-being, and quality of life, as well as health care costs. It is often the impetus for an older adult leaving his or her independent living environment and moving into assisted living (**Touhy & Jett, 2010**).

Dry AMD is more common and progresses at a faster rate among smokers than among nonsmokers (**Noble & Chaudhary, 2010**). Other risk factors include hypertension, female gender, short stature, family history, and a long-term diet poor in carotene and vitamin E (National Eye Institute, 2010).

Another cause of AMD is the growth of new blood vessels in the macula, which have thin walls and leak blood and fluid (*wet* AMD). Exudative macular degeneration is also a type of wet macular degeneration but can occur at any age. The condition can occur in only one eye or in both eyes. In addition, the person with AMD can also develop exudative macular degeneration. Patients with exudative degeneration have a sudden decrease in vision after a serous detachment of pigment epithelium in the macula. Newly formed blood vessels invade this injured area and cause fluid and blood to collect under the macula (like a blister), resulting in scar formation and visual distortion.

PATIENT-CENTERED COLLABORATIVE CARE

Dry AMD has no cure. Management of dry AMD is focused on slowing the progression of the vision loss and helping the patient maximize remaining vision (**Watkinson, 2010**). Current research findings suggest that the risk for dry macular degeneration can be reduced by increasing long-term dietary intake of antioxidants, vitamin B₁₂, and the carotenoids *lutein* and *zeaxanthin*. The same dietary treatments appear to slow the progression of macular degeneration.

The loss of central vision reduces the ability to read, write, recognize safety hazards, and drive. Suggest alternative strategies (e.g., large-print books, public transportation) and referrals to community organizations that provide a wide range of adaptive equipment. See pp. 1073-1075 of Patient-Centered Collaborative Care in the Reduced Vision section for a complete discussion of patient care needs.

Management of patients with exudative or wet macular degeneration is geared toward slowing the process and identifying further changes in visual perception. Fluid and blood may resorb in some patients with exudative degeneration. Laser therapy to seal the leaking blood vessels in or near the macula can limit the extent of the damage. Recent clinical trials with agents that slow or prevent new blood vessel formation, the vascular endothelial growth factor inhibitors (VEGFIs), have shown success in the management of wet macular degeneration. This therapy uses either bevacizumab (Avastin), which is a drug used as targeted therapy for cancer, or ranibizumab (Lucentis), which is a VEGFI approved specifically for ocular problems. Management involves monthly injections of the drug into the vitreal chamber. The results were a reduction of vitreal fluids and an increase in visual acuity (Tao et al., 2010).

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

The patient is an 82-year-old woman who has just been diagnosed as having early-stage dry age-related macular degeneration (AMD). She is 5 feet tall and weighs 180 pounds. Her other health problems include type 2 diabetes and moderate hypertension. She is shocked at the diagnosis and sobs almost uncontrollably. When you ask her what she knows about AMD, she tries to stop crying and lights up a cigarette. She tells you that her mother and older sister both “went blind” with AMD and had to move into assisted living. She also tells you that she is the driver for her social group, her favorite pastimes are reading and playing cards, and she dreads the thought of giving up driving. Her final statement is “I’ll probably be blind by this time next year.”

1. What risk factors does this patient have for age-related dry macular degeneration?
2. Is her fear of inevitable blindness valid?
3. Does she have to stop driving now? Why or why not?
4. What will you tell her about macular degeneration?

RETINAL HOLES, TEARS, AND DETACHMENTS

Pathophysiology

A **retinal hole** is a break in the retina. These holes can be caused by trauma or can occur with aging. A **retinal tear** is a more jagged and irregularly shaped break in the retina. It can result from traction on the retina. A **retinal detachment** is the separation of the retina from the epithelium. Detachments are classified by the nature of their development.

Rhegmatogenous detachments occur following a hole or tear in the retina caused by mechanical force, creating an opening for the vitreous to move under the retina. When sufficient fluid collects in this space, the retina detaches. *Traction* detachments occur when the retina is pulled away from the support tissue by bands of fibrous tissue in the vitreous. *Exudative* detachments are caused by fluid collecting under the retina. These often occur with a systemic disease or with ocular tumors. No retinal break occurs.

PATIENT-CENTERED COLLABORATIVE CARE

The onset of a retinal detachment is usually sudden and painless because no pain fibers are located in the retina. Patients may suddenly see bright flashes of light (**photopsia**) or floating dark spots in the affected eye. During the initial phase of the detachment or if the detachment is partial, the patient may describe the sensation of a curtain being pulled over part of the visual field. The visual field loss corresponds to the area of detachment.

On ophthalmoscopic examination, detachments are seen as gray bulges or folds in the retina that quiver. Depending on the cause of the detachment, a hole or tear also may be seen at the edge of the detachment.

If a retinal hole or tear is discovered before it causes a detachment, the defect may be closed or sealed. Closure prevents fluid from collecting under the retina and reduces the risk for a detachment. Treatment involves creating an inflammatory response that will bind the retina and choroid together around the break. The inflammatory response can be created using **cryotherapy** (a freezing probe), **photocoagulation** (laser), or **diathermy** (high-frequency current).

Spontaneous reattachment of the retina is rare. Surgical repair is needed to place the retina in contact with the underlying structures. A common repair procedure is scleral buckling.

Preoperative Care

The patient is usually anxious and fearful about a possible permanent loss of vision. *Nursing priorities include providing information and reassurance to allay fears.*

Instruct the patient to restrict activity and head movement before surgery to prevent further tearing or detachment and to promote drainage of any fluid under the retina. An eye patch is placed over the affected eye to reduce eye movement. Topical drugs are given before surgery to inhibit pupil constriction and accommodation.

Operative Procedures

The surgery is performed with the patient under general anesthesia. In scleral buckling, the ophthalmologist repairs wrinkles or folds in the retina so that the retina can assume its normal smooth position. To promote reattachment, a small piece of silicone is placed against the sclera and held in place by an encircling band (which is the actual “buckle”). This device keeps the retina in contact with the choroid and sclera to promote attachment. Any fluid under the retina is drained.

A gas or silicone oil placed inside the eye can be used to promote retinal reattachment. These agents float up against the retina to hold it in place until healing occurs.

Postoperative Care

After surgery, an eye patch and shield usually are applied. Monitor the patient’s vital signs, and check the eye patch and shield for any drainage.

Activity after surgery varies. If gas or oil has been placed in the eye, position the patient on his or her abdomen. Instruct the patient to lie with the head turned so that the affected eye is facing up, for several days or until the gas has been absorbed. As an alternative, he or she can sit on the side of the bed and place the head on an over-the-bed table.

Give drugs as prescribed for pain and nausea. Teach the patient to report any sudden increase in pain or pain occurring with nausea. Report these symptoms to the surgeon immediately because they may indicate the development of complications. Remind the patient to avoid activities that increase intraocular pressure (IOP) (see [Table 49-1](#)).

Teach the patient to avoid reading, writing, and close work, such as sewing, in the first week after surgery because these activities cause rapid eye movements and promote detachment. Teach him or her the manifestations of infection and detachment (sudden reduced visual acuity, eye pain, pupil that does not respond to light by constricting). Instruct the patient to notify the surgeon immediately if these manifestations occur.

RETINITIS PIGMENTOSA

Several types of retinal disorders can cause progressive degeneration of the retina and lead to blindness. Retinitis pigmentosa (RP) is a condition in which retinal nerve cells degenerate and the pigmented cells of the retina grow and move into the sensory areas of the retina, causing further degeneration.

GENETIC/GENOMIC CONSIDERATIONS

Different forms of retinitis pigmentosa can be inherited as an autosomal dominant (AD) trait, an autosomal recessive (AR) trait, or an X-linked recessive trait (Nussbaum et al., 2007). Mutations in more than 20 genes have been identified as being responsible for retinitis pigmentosa, and gene testing for more than 800 mutations of the AR and AD forms of the problem is commercially available.

The earliest manifestation of RP is night blindness, often occurring in childhood. Over time, decreased visual acuity progresses to total blindness. Examination of the retina shows heavy pigmentation in a lacy pattern. Cataracts may accompany this disorder.

No current therapy is effective in preventing the degenerative process. Current management strategies focus on protecting active retinal cells and slowing the progression of disease. Teach patients with RP to avoid drugs that are known to adversely affect retinal cells, such as isotretinoin (Accutane) and drugs for erectile dysfunction (e.g., sildenafil [Viagra]). Also remind them to wear eyeglasses that provide ultraviolet protection. The ingestion of 15,000 international units of vitamin A daily is recommended to slow the progression of the disorder, as is the daily ingestion of docosahexaenoic acid (DHA), an omega-3 fatty acid and antioxidant (Foundation Fighting Blindness, 2010). Additional supplements that appear to slow the progression of RP include beta carotene, lutein, and zeaxanthin. When macular edema is present, oral acetazolamide (Diamox) can reduce the edema. Cataract surgery and lens replacement is recommended when cataracts further reduce vision. Other treatments under investigation include retinal microchip implantation, retinal tissue transplantation, and stem cell therapy.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client whose sister was just diagnosed with autosomal recessive retinitis pigmentosa is pregnant with a male fetus. The client's husband has no relatives with the disorder. She asks what the chances are that her son could be affected. What is the nurse's best response?

- "Because it is likely that you are a carrier and your husband does not have any affected relatives, only your daughters can develop the disease."
- "Because it is likely that you are a carrier and your husband does not have any affected relatives, none of your children will have the disease but each child will have a 50% risk for being a carrier."
- "Because your sister actually has retinitis pigmentosa, the risk for your children having the disorder is 50% with each pregnancy."
- "Because you are a woman, your daughters will each have a 50% risk for having the disease, and all of your sons will be carriers."

REFRACTIVE ERRORS

Pathophysiology

The ability of the eye to focus images on the retina depends on the length of the eye from front to back and the refractive power of the lens system. **Refraction** is the bending of light rays. Problems in either eye length or refraction can result in refractive errors.

Myopia is nearsightedness, in which the eye over-refracts the light and the bent images fall in front of, not on, the

retina. **Hyperopia**, also called *hypermetropia*, is farsightedness, in which refraction is too weak, causing images to be focused behind the retina. **Presbyopia** is the age-related problem in which the lens loses its elasticity and is less able to change shape to focus the eye for close work. As a result, images fall behind the retina. This problem usually begins in people in their 30s and 40s. **Astigmatism** occurs when the curve of the cornea is uneven. Because light rays are not refracted equally in all directions, the image does not focus on the retina.

PATIENT-CENTERED COLLABORATIVE CARE

Refractive errors are diagnosed through a process known as **refraction**. The patient is asked to view an eye chart while lenses of different strengths are systematically placed in front of the eye. With each lens strength, he or she is asked whether the lenses sharpen or worsen vision. The strength of the lens needed to focus the image on the retina is expressed in measurements called *diopters*.

Nonsurgical Management

Refractive errors are corrected with a lens that focuses light rays on the retina (see Fig. 48-5 in Chapter 48). Hyperopic vision is corrected with a convex lens that moves the image forward. Myopic vision is corrected with a biconcave lens to move the focused image back to the retina.

Eyeglasses are used to correct refractive errors. They are easy to use, durable, and relatively low cost. Disadvantages are a change in appearance, the weight of the frame on the nose, and reduced peripheral vision (only central vision is corrected with eyeglasses).

Contact lenses also correct refractive errors. Round plastic disks rest against the cornea and fit under the eyelid. Hard contact lenses correct errors in two ways—by changing the shape of the cornea and by providing direct refraction. Changing corneal shape increases its refracting ability. Direct refraction from the contact lens places the specific refractive power and shape needed in front of the eye so that light rays are correctly focused onto the retina.

Complications of hard contact lens wear include corneal edema, which occurs when the lenses are worn for an extended period. Corneal abrasion can result from overwear, which dries the cornea and causes small breaks, or from the irritation of the contact lens against the cornea.

Soft contact lenses are better tolerated than hard contact lenses. They are about the thickness of plastic wrap and can be worn for longer periods because they allow greater corneal access to moisture and oxygen. Problems with soft lenses are related to lens deterioration, deposits in the lens, and failure to follow correct lens care practices.

There are two types of soft contact lenses: daily-wear lenses (worn only during waking hours) and extended-wear lenses. Extended-wear contact lenses are worn continuously for days to several weeks, depending on the patient's environment, activities, and tolerance of the lenses.

Surgical Management

Surgery is a popular alternative for the treatment of refractive errors. The most common vision-enhancing surgery is laser in-situ keratomileusis (LASIK). This procedure is much more

expensive than eyeglasses or any type of contact lens, and it is rarely covered by insurance.

LASIK can correct nearsightedness, farsightedness, and astigmatism using the excimer laser. The superficial layers of the cornea are lifted temporarily as a flap, and brief but powerful laser pulses reshape the deeper corneal layers. After reshaping is complete, the corneal flap is placed back into its original position.

Usually both eyes are treated at the same time, which is most convenient for the patient, although this practice has some risks. If the laser malfunctions or if instruments are contaminated, the vision in both eyes could be adversely affected (Ayers, 2010). Many patients have improved vision within an hour after surgery, although complete healing to best vision may take up to 4 weeks. The outer corneal layer is not damaged, and pain is minimal.

After LASIK correction of refractive errors, many patients no longer require eyeglasses or contact lenses. Overcorrection or undercorrection is possible, however, and some patients may need a mild prescription for a continued refractive error.

Complications include corneal clouding, chronic dry eyes, and refractive errors. Some patients have developed blurred vision and other refractive errors months to years after this surgery as a result of keratectasia. This problem is related to the formation of the corneal flap during surgery and laser-thinning of the cornea. The cornea then becomes unstable and does not refract appropriately.

Although it is a relatively safe procedure, not everyone should have LASIK. People for whom risks may outweigh benefits of LASIK surgery include anyone who has a disorder or is taking drugs that delay wound healing (e.g., human immune deficiency virus [HIV] disease, rheumatoid arthritis, other autoimmune diseases, diabetes), those whose refractive errors are unstable and require yearly changes in prescriptive correction, those who routinely engage in contact sports, those who have thin corneas, and those who have any type of dry eye syndrome (Ayers, 2010).

Another procedure, Intacs corneal ring placement, can enhance vision for nearsightedness. However, this procedure is most often performed for keratoconus. For more information about the procedure, see surgical intervention for keratoconus on p. 1058.

TRAUMA

Trauma to the eye or orbital area can result from almost any activity. Care varies depending on the area of the eye affected and whether the globe of the eye has been penetrated.

Hyphema

A **hyphema** is a hemorrhage in the anterior chamber occurring when a force is applied to the eye and breaks the blood vessels. If the hyphema is large, it may block the pupil and reduce vision, possibly causing pain and photophobia. Hemolysis of the blood occurs, and the blood is filtered out of the eye through the trabecular meshwork. If the blood particles obstruct the meshwork, increased intraocular pressure (IOP) results.

Management includes bedrest in semi-Fowler's position to use gravity as an aid in keeping the hyphema away from the optical center of the cornea. Minimal or no sudden eye movements are permitted for 3 to 5 days to decrease the risk for

rebleeding. Cycloplegic (paralyzing) eyedrops may be prescribed, and the eye is protected by a patch and shield. Television and reading are restricted. A hyphema usually resolves in 5 to 7 days.

Contusion

A contusion of the eyeball and surrounding tissue is caused by traumatic contact with a blunt object. The force of the blow pushes the eye back in the socket. The globe is compressed, and stretching of the ocular soft tissues occurs, which can damage and possibly rupture the globe. Results of the injury may not be immediate and include edema of the eyelids, subconjunctival hemorrhage, corneal edema, and hyphema.

Periorbital ecchymosis, or "black eye," a common contusion injury, is usually caused by blunt trauma. Bleeding into the soft tissue occurs, creating the bruise. The color fades gradually and disappears in 10 to 14 days. Visual acuity is usually not affected, although orbital pain, photophobia, eyelid edema, and diplopia may be present.

Treatment begins at the time of injury. Ice is applied immediately. The patient should have a thorough eye examination to rule out any other eye injuries.

Foreign Bodies

Eyelashes, dust, fingernails, dirt, and airborne particles can come in contact with the conjunctiva or cornea and irritate or abrade the surface. If nothing is seen on the cornea or conjunctiva, the eyelid is everted to examine the conjunctivae. The patient usually has a feeling of something being in the eye and may have blurred vision. Pain occurs if the corneal surface is injured. Tearing and photophobia may be present.

Evaluation of vision is done before treatment. The eye of any patient with a suspected corneal abrasion is examined with fluorescein, followed by irrigation with normal saline (0.9%) to gently remove the particles. Best practices for ocular irrigation are listed in [Chart 49-8](#).

If an eye patch is applied after the foreign body is removed, tell the patient how long the patch must be left in place. Follow-up with the ophthalmologist is needed.

Lacerations

Lacerations are wounds caused by sharp objects and projectiles. The injury can occur to any part of the eye, but the most commonly injured areas are the eyelids and the cornea.

Initially, close the eye and apply a small ice pack to decrease bleeding. The patient should receive medical attention as soon as possible. If the patient can open the eye, check visual acuity and clean the eyelids. Minor lacerations of the eyelid can be sutured in an emergency department, an urgent care center, or an ophthalmologist's office. A microscope is needed in the operating room if the patient has a laceration that involves the eyelid margin, affects the lacrimal system, involves a large area, or has jagged edges.

Corneal lacerations are an emergency because eye contents may prolapse through the laceration. Manifestations include severe eye pain, photophobia, tearing, decreased visual acuity, and inability to open the eyelid. If the laceration is the result of a penetrating injury, an object may be seen protruding from the eye. *The object is removed only by the ophthalmologist, because it may be holding eye structures in place.*

CHART 49-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Ocular Irrigation

1. Assemble equipment:
 - Normal saline IV (1000-mL bag)
 - Macro drip IV tubing
 - IV pole
 - Eyelid speculum
 - Topical anesthetic (proparacaine hydrochloride)
 - Gloves
 - Collection receptacle (emesis basin works well)
 - Towels
 - pH paper
2. Quickly obtain a history from the patient while flushing the tubing with normal saline:
 - Nature and time of the injury
 - Type of irritant or chemical (if known)
 - Type of first aid administered at the scene
 - Any allergies to the “caine” family of medications
3. Evaluate the patient’s visual acuity *before* treatment:
 - Ask the patient to read your name tag with the affected eye while covering the good eye.
 - Ask the patient to “count fingers” with the affected eye while covering the good eye.
4. Put on gloves.
5. Place a strip of pH paper in the cul-de-sac of the patient’s affected eye to test the pH of the agent splashed into the eye and to know when it has been washed out.
6. Instill proparacaine hydrochloride eyedrops as prescribed.
7. Place the patient in a supine position with the head turned slightly toward the affected eye.
8. Have the patient hold the affected eye open, or position an eyelid speculum.
9. Direct the flow of normal saline across the affected eye from the nasal corner of the eye toward the outer corner of the eye.
10. Assess the patient’s comfort during the procedure.
11. If both eyes are affected, irrigate them simultaneously using separate personnel and equipment.

Antibiotics are given to reduce the risk for infection. Depending on the depth of the laceration, scarring may develop. If the scar alters vision, a corneal transplant may be needed later. If the eye contents have prolapsed through the laceration or if the injury is severe, **enucleation** (surgical eye removal) may be indicated.

Penetrating Injuries

Patients with penetrating eye injuries have the poorest chance of retaining vision in the injured eye. Glass, high-speed metal or wood particles, BB pellets, and bullets are common causes of penetrating injuries. The particles can enter the eye and lodge in or behind the eyeball.

The patient has eye pain and reports “I suddenly felt something hit my eye.” An entrance wound may be visible. Depending on where the object enters and rests within the eye, vision may be affected.

X-rays and computed tomography (CT) scans of the orbit are usually performed. Computer-generated reconstructions of the CT images are created to study this complex area to ensure the orbit is intact and to look for fractures that might entrap orbital muscles. *Magnetic resonance imaging (MRI) is contraindicated because the procedure may move any metal-containing projectile and cause more injury.*

Surgery is usually needed to remove the foreign object. In some cases, foreign bodies need to be removed by a vitrectomy. IV antibiotics are started before surgery to reduce the risk for infection. A tetanus booster is given if necessary.

Assess and document visual acuity. If the patient cannot see print, determine whether he or she can count fingers or see hand motions. If the patient cannot see movement, assess his or her ability to see light.

OCULAR MELANOMA

Pathophysiology

Melanoma is the most common malignant eye tumor in adults ([American Cancer Society, 2011](#); [Simar, 2009](#)). This tumor occurs most often in the uveal tract among people in their 30s and 40s and is associated with exposure to ultraviolet (UV) light. Because of its rich blood supply, a melanoma can spread by extension through the sclera or invasion into nearby tissue and the brain.

PATIENT-CENTERED COLLABORATIVE CARE

Manifestations of melanoma may not be readily apparent; the tumor may be discovered during a routine examination. Blurred vision may occur if the macular area is invaded. Visual acuity is reduced if the tumor grows inward toward the center of the eye from the choroid and alters the visual pathway. Increased intraocular pressure (IOP) can result if the tumor obstructs flow of aqueous humor. Iris color changes when the tumor infiltrates the iris. Sudden loss of a visual field may result from tumor invasion that causes retinal detachment.

Diagnostic tests for a melanoma depend on the size and tumor growth rate. Ultrasonography or MRI is performed to determine the tumor’s location and size. Treatment depends on the tumor’s size and growth rate, as well as the condition of the other eye. Small iris lesions are monitored until growth is observed. Tumors of the choroid are treated by surgical enucleation or by radiation therapy with a radioactive plaque ([Simar, 2009](#)).

Enucleation (surgical removal of the entire eyeball) is the most common surgery for ocular melanoma and is performed under general anesthesia. After the eye is removed, a ball implant is inserted as a base for the socket prosthesis.

The implant is covered with surrounding tissue, muscles, and conjunctiva. A plastic conformer is placed over the conjunctiva to maintain the shape of the eyelids until a prosthesis can be fitted. After the dressing is removed, a pressure patch is placed over the eye for 24 hours.

Until the prosthesis is fitted (after about 1 month), an antibiotic-steroid ointment is inserted into the cul-de-sac once daily. Best practices for prosthesis care are listed in [Chart 49-9](#).

Radiation therapy is an “eye-sparing” procedure that can reduce the size and thickness of melanomas but rarely eliminates the tumors completely. The radioactive plaque—a round, flat disk about the size of a dime and containing a radioactive material—is sutured to the sclera overlying the tumor site. The length of time the plaque remains sutured to the sclera depends on the size of the tumor and the dose of radiation to be delivered.

CHART 49-9 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Insertion and Removal of an Ocular Prosthesis**Insertion**

1. Assemble equipment:
 - Prosthesis
 - Gloves
 - Towel
2. Explain the procedure to the patient.
3. Wash your hands.
4. Cover the work area with a cloth or towel.
5. Don gloves.
6. Remove the prosthesis from its container, and rinse it with warm water.
7. Lift the patient's upper lid using your nondominant hand.

8. Place the prosthesis between the thumb and forefinger of your dominant hand. The notched end of the prosthesis should be closest to the patient's nose.

9. Insert the prosthesis with the top edge slipping under the upper lid. Continue until most of the iris is covered by the upper lid.

10. Gently release the upper eyelid.
11. Retract the lower lid slightly until the bottom edge of the prosthesis slips behind it.

12. Release your hands slowly.

Removal

1. Assemble equipment:
 - Normal saline-filled, labeled container
 - Gloves
2. Explain the procedure to the patient.
3. Wash your hands.
4. Don gloves.
5. Instruct the patient to sit up and tilt the head slightly downward.
6. Place your hand against the patient's cheek, palm side up.
7. Pull the lower lid slightly down and laterally.
8. Allow the prosthesis to slide out onto your hand, or pull gently if necessary.
9. Place the prosthesis in a container filled with normal saline labeled with the patient's name. Cover the container.

Complications of radiation therapy include vascular changes, retinopathy, glaucoma, necrosis of the sclera, and cataract formation. Vitreous hemorrhage may develop as the tumor becomes smaller and pulls or breaks blood vessels.

While the plaque is in place, an eye patch may or may not be used. Cycloplegic eyedrops and an antibiotic-steroid combination are given. Teach the patient how to instill eyedrops.

REDUCED VISION**Pathophysiology**

Different forms of reduced vision may affect any or all aspects of vision, including color, light, image, movement, and acuity. Reduced vision may be temporary, such as when cataracts obscure vision but surgery has not yet been planned or performed. Patients are legally blind if their best visual acuity with corrective lenses is 20/200 or less in the better eye or if the widest diameter of the visual field in that eye is no greater than 20 degrees.

Blindness can occur in one or both eyes. When one eye is affected, the field of vision is narrowed and depth perception is impaired. Central vision can be impaired by diseases involving the macula, such as macular edema or macular degeneration. Loss of peripheral vision occurs with glaucoma. The loss of side vision affects the patient's ability to drive and awareness of hazards in the periphery.

PATIENT-CENTERED COLLABORATIVE CARE

Priorities for nursing involve teaching the patient techniques to make better use of existing vision (Watkinson, 2009). Moving the head slightly up and down can enhance a three-dimensional effect. When shaking hands or pouring water, the patient can line up the object and move toward it. He or she should choose a position that favors the eye with better vision. For example, people with vision in the right eye should position people and items on their right.

CHART 49-10 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Providing Care to the Patient with Reduced Vision

- Always knock or announce your entrance into the patient's room or area and introduce yourself.
- Ensure that all members of the health care team also use this courtesy of announcement and introduction.
- Ensure that the patient's reduced vision is noted in the medical record, is communicated to all staff, is marked on the call board, and is identified on the door of the patient's room.
- Determine to what degree the patient can see anything.
- Orient the patient to the environment, counting steps with him or her to the bathroom.
- Assist the patient in placing objects on the bedside table or in the bed and around the bed and room, and do not move them without the patient's permission.
- Remove all objects and clutter between the patient's bed and the bathroom.
- Ask the patient what type of assistance he or she prefers for grooming, toileting, eating, and ambulating, and communicate these preferences with the staff.
- Describe food placement on a plate in terms of a clock face.
- Open milk cartons; open salt, pepper, and condiment packages; and remove lids from cups and bowls.
- Unless the patient also has a hearing problem, use a normal tone of voice when speaking.
- When walking with the patient, offer him or her your arm and walk a step ahead.

Nursing interventions for the patient with reduced sight focus on communication, safety, ambulation, self-care, and support (Watkinson, 2009). Chart 49-10 lists ways to help patients with reduced vision to function as independently as possible.

Communication is important in helping the patient remain independent and connected to the world. Reduced vision is a common occurrence, and many adaptive devices are available to help the person maintain independence. Many towns and cities have auditory traffic signals so that persons with reduced vision can know when it is safe to cross a street. Curbs in these areas may have high-contrast color paint to let the person know when to step up or down. Libraries have large-print books and books on tape. "Talking" clocks, watches, and timers are available. Playing cards, games, restaurant menus, calendars, and instruction booklets are available in large print sizes. Computer keyboards with high contrast and larger letters in the keys are available, as are large screens. Direct the patient with reduced vision to the local resources to obtain adaptive items and to learn how to use them (Watkinson, 2009).

Safety is a major issue for the person with reduced vision. For patients at home with reduced vision, the home is the place where they feel most safe. They are familiar with room and item location. For example, they may have counted the number of footsteps needed to move from one area to another within the home. It is important to stress to family and friends that changes in item location should not be made without input from the person with reduced vision.

Even people who have experienced gradually reduced vision over time and who have had time to adjust may benefit from having a person with vision assist in making adaptations in the home. Adaptations may include the following:

- Using tape and a heavy black marker, mark the 350-degree temperature setting on the oven and mark the 70-degree temperature setting on the heating or cooling thermostat.
- Paint or mark light switches in a deep color that contrasts with the surrounding wall.
- Label canned goods with large, bold, black letters on white tape.
- Teach the patient to feel for the crease in paper milk cartons that indicates the place to open the spout.
- Help the patient differentiate different drugs by altering the shape or contours of a bottle. Rubber bands can be wound around a bottle to change its texture. Raised symbols can be glued to caps to make identification easier.

The patient is most at risk for safety problems in an unfamiliar or changing environment. When a person with reduced vision must be hospitalized, promote safety and independence by orienting him or her to the new environment.

Most people with reduced vision had sight at some time and have background knowledge regarding size and shape that can be used when providing information. Many blind people have some degree of sight. When talking with a person who has limited sight or is blind, always use a normal tone of voice unless he or she has a hearing problem.

First orient the patient to the immediate environment, including the size of the room. Use one object in the room, such as a chair or hospital bed, as the focal point during your description. Guide the person to the focal point, and orient him or her to the environment from that point. For example, you might say, "To the left of the bed is a chair." Then describe all other objects in relation to the focal point. Go with the patient to other important areas, such as the bathroom, so that he or she can learn their locations. Highlight the location of the toilet, sink, and toilet paper holder. *Never leave the patient with reduced vision in the center of an unfamiliar room.*

Patients with reduced vision prefer to establish the location of important objects, such as the call light, water pitcher, and clock. Once their location has been fixed, do not move these items without the patient's consent. Do not move the location of chairs, stools, and wastebaskets without consulting the patient.

At mealtime, set up food on the tray using clock placement. For example, "There is sliced ham at the 6 o'clock position; peas are located at the 3 o'clock position; to the right of the plate is coffee; salt and pepper are next to the coffee."

Ambulation with a patient who has reduced vision involves allowing him or her to grasp your arm at the elbow. Keep the arm close to your body so that he or she can detect your direction of movement. Alert the patient when obstacles are in the path ahead.

Patients may use a cane to detect obstacles, such as furniture, walls, or curbs. The cane is held in the dominant hand several inches off the floor and sweeps the ground where his or her foot will be placed next. The laser cane sends out signals to help detect obstacles.

Self-care and the ability to control the environment are important. Knock on the door before entering the hospital room or any other environment of a patient with reduced vision. State your name and the reason for visiting when entering the room. Coordinate with other members of the health care team to ensure this etiquette is used consistently.

Mark the door to the room to indicate it is occupied by a person with reduced vision.

Support is needed, especially when the reduced vision is of sudden onset and may be permanent. Patients' reactions to the loss of sight are similar to the reaction to loss of a body part. Allow the newly blind person a period of grieving for the "dead" (nonseeing) eye. He or she may feel hopeless and angry. With time, anger usually gives way to acceptance. The ability to cope may begin within days, but some patients mourn for months or years.

Patients benefit from the honest support that you can provide. They need to hear that it is normal to mourn, to cry, and to feel the loss. Help them move toward acceptance by encouraging the mastery of one task at a time and by providing positive reinforcement for each success.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

A client with reduced vision who is 1 day postoperative for a non-vision problem expresses concern to the nurse that he is afraid if a hospital fire occurred he would not be able to get out in time. Which nurse response or action is most likely to allay his fears?

- A. Demonstrating how to close the door and place wet towels at the bottom edge of the door.
- B. Reminding him that the hospital meets all current fire codes and has never experienced a major fire.
- C. Helping him count the steps to the stairway exit and reminding him that he is on the second floor.
- D. Reassuring him that even if a fire broke out, the nurses and other personnel would stay on the unit with him.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing reduced sensation as a result of vision problems?

Perform and interpret focused physical assessment findings, including:

- Patient squints or tilts the head when viewing objects or print at a distance.
- Patient closes one eye to read or see at a distance.
- Patient moves reading materials either very close to his or her face or as far away from the face as he or she can reach.
- Patient may not startle when a sudden move is made at the face.
- Pupils are unequal and may not react to light.
- Eyes do not focus on a distant object and track it as it is moved closer to the face.
- Red reflex may be absent or present in only one eye.
- Appearance is disheveled with buttons not properly buttoned and clothing colors or patterns not complementary.
- Patient does not make eye contact and turns head toward sounds rather than sights.
- Patient walks with hesitation into a room or bumps into objects in his or her path.
- Patient may seem confused about time and place.

What should you INTERPRET and how should you RESPOND to a patient experiencing reduced sensation as a result of vision problems?

Interpret by:

- Assessing visual acuity with a Snellen chart, counting fingers, hand motion, or light perception.
- Asking the patient to describe the objects in the room and their colors.
- Asking the patient what he or she can see well and what is more difficult to see.

Respond by:

- Orienting the patient to the immediate surroundings.
- Offering your arm for the patient to hold when he or she is moving to a different location.
- Not leaving the patient alone in the center of a strange room.
- Asking him or her what assistance is needed for independent activity.
- Assessing the immediate environment for safety hazards and removing the hazard.

On what should you REFLECT?

- Consider what environmental changes could make the unit safer or more manageable for a person with reduced vision.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category

Safe and Effective Care Environment

- Use gloves when examining an eye with drainage from the eye or tear duct.
- Avoid performing an ophthalmoscopic examination on a confused patient.
- Orient the patient with reduced vision to his or her immediate surroundings, including how to call for help and where the bathroom is located.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Identify the room of a patient with reduced vision (without identifying the patient).

Health Promotion and Maintenance

- Identify people at risk for vision problems as a result of work environment or leisure activities, and teach them specific ways to protect the eyes.
- Encourage all patients to wear eye protection when they are performing yard work, are working in a woodshop or metal shop, are using chemicals, or are in any environment in which drops or particulate matter is airborne.
- Encourage all adult patients older than 40 years to have an eye examination with measurement of intraocular pressure every year.
- Encourage everyone to use polarizing sunglasses whenever outdoors in bright sunlight.
- Teach all patients to wash their hands before and after touching the eyes.

Psychosocial Integrity

- Use a normal tone of voice to talk with a patient who has a vision problem and normal hearing.

- Knock on the door before entering the room of a patient with reduced vision, and introduce yourself.
- Allow the patient and family the opportunity to express concerns about a vision change.
- Refer patients newly diagnosed with visual impairment to appropriate local resources and support groups.

Physiological Integrity

- Ask the patient about vision problems in any other members of the family, because many vision problems have a genetic component.
- Teach patients the proper techniques for self-instillation of eyedrops and eye ointment.
- Stress the importance of completing an antibiotic regimen for an eye infection.
- Teach patients who are at risk for increased intraocular pressure what activities to avoid (see [Table 49-1](#)).
- Teach patients with an infection of the eye or eyelid not to rub the eye (to avoid infecting the other eye).
- Never attempt to remove any object protruding from the eye.

Assessment of the Ear and Hearing

Decision-Making Challenges

Audio Glossary

Key Points

Review Questions for the NCLEX® Examination

Video Clip: Ear Canal

Video Clip: External Ear

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Apply principles of infection control when examining an ear with drainage.

Health Promotion and Maintenance

2. Teach all people how to perform ear hygiene safely.
3. Teach all people to use ear protection equipment and strategies.

Psychosocial Integrity

4. Teach patients and family members about what to expect during tests and procedures to assess ear and hearing problems.
5. Provide opportunities for the patient and family to express feelings and concerns about a possible change in hearing.

Physiological Integrity

6. Identify people at risk for hearing problems as a result of drug therapy, genetic predisposition, or exposure to environmental hazards.
7. Perform a clinical ear and hearing assessment, including health history and psychosocial assessment.
8. Describe adaptations needed when caring for patients who have age-related changes in the structure of the ear and hearing.
9. Identify 10 common drugs that affect hearing.
10. Demonstrate the correct use of an otoscope.

The ear and the brain together allow hearing. Hearing is one of the five senses important for communicating with the world. Functional hearing assists in the concepts of sensation and cognition. It is used to assess surroundings, allow independence, warn of danger, appreciate music, work, play, and interact with other people.

Ear and hearing problems are common among adults of all ages. Assessment of the ear and hearing is an important skill for nurses in any care environment. Therefore an understanding of the anatomy and physiology of the ear is essential. Many ear and hearing problems develop over long periods and may be affected by drugs or systemic health problems.

ANATOMY AND PHYSIOLOGY REVIEW

Structure

The ear has three divisions: the external ear, the middle ear, and the inner ear. Each part is important to hearing.

External Ear

The external ear develops in the embryo at the same time as the kidneys and urinary tract. Thus any person with a defect of the external ear should be examined for possible problems of the kidney and urinary systems.

The **pinna** is the part of the external ear that is composed of cartilage covered by skin and attached to the head at about

a 10-degree angle. It is embedded in the temporal bone on both sides of the head at the level of the eyes. The external ear also includes the **mastoid process**, which is the bony ridge located over the temporal bone behind the pinna. The external ear extends from the pinna through the external ear canal to the **tympanic membrane** (eardrum) (Fig. 50-1). The ear canal is slightly S-shaped and lined with **cerumen** (wax)-producing glands, sebaceous glands, and hair follicles. Cerumen helps protect and lubricate the ear canal. The hair follicles and cerumen protect the eardrum and the middle ear. The distance from the opening of the ear canal to the eardrum in an adult is 1 to 1½ inches (2.5 to 3.75 cm).

Middle Ear

The middle ear begins at the medial or inner side of the eardrum. The eardrum separates the external ear and the middle ear.

The middle ear consists of a compartment called the **epitympanum**. Located in the epitympanum are the top opening of the eustachian tube and three small bones known as the

bony ossicles, which are the **malleus** (hammer), the **incus** (anvil), and the **stapes** (stirrup) (Fig. 50-2). The bony ossicles are joined loosely, thereby moving with vibrations created when sound waves hit the eardrum.

The eardrum, a thick sheet of tissue, is transparent, opaque, or pearly gray and moves when air is injected into the external canal. The landmarks on the eardrum include the **annulus**, the **pars flaccida**, and the **pars tensa**. These correspond to the parts of the malleus that can be seen through the transparent eardrum. The eardrum is attached to the first bony ossicle, the malleus, at the umbo (Fig. 50-3). The umbo is seen

FIG. 50-1 Anatomic features of the external ear.

FIG. 50-3 Landmarks on the tympanic membrane.

FIG. 50-2 Anatomic features of the middle and inner ear.

through the eardrum membrane as a white dot and is one end of the long process of the malleus. The pars flaccida is that portion of the eardrum above the short process of the malleus. The pars tensa is that portion surrounding the long process of the malleus.

The middle ear is separated from the inner ear by the round window and the oval window. The eustachian tube begins at the floor of the middle ear and extends to the throat. The tube opening in the throat is surrounded by adenoid lymphatic tissue (Fig. 50-4). The eustachian tube allows the pressure on both sides of the eardrum to equalize. Secretions from the middle ear drain through the tube into the throat.

Inner Ear

The inner ear is on the other side of the oval window and contains the semicircular canals, the cochlea, the vestibule, and the distal end of the eighth cranial nerve (see Fig. 50-2). The **semicircular canals** are tubes made of cartilage and contain fluid and hair cells. These canals are connected to the sensory nerve fibers of the vestibular portion of the eighth cranial nerve. The fluid and hair cells within the canals help maintain the sense of balance.

The **cochlea**, the spiral organ of hearing, is divided into the scala tympani and the scala vestibuli. The scala media is filled with *endolymph*, and the scala tympani and scala vestibuli are filled with *perilymph*. These fluids protect the cochlea and the semicircular canals by allowing these structures to “float” in the fluids and be cushioned against abrupt head movements.

The **organ of Corti** is the receptor of hearing located on the basilar membrane of the cochlea. The cochlea contains hair cells that detect vibration from sound and stimulate the eighth cranial nerve.

The **vestibule** is a small, oval-shaped, bony chamber between the semicircular canals and the cochlea. It contains the utricle and the saccule, organs that are important for balance.

Function

Hearing is the main function of the ear and occurs when sound is delivered through the air to the external ear canal and the temporal bone covering the mastoid air cells. The sound waves strike the mastoid and the movable eardrum, creating vibrations. The eardrum is connected to the first bony ossicle, which allows the sound wave vibrations to be transferred from the eardrum to the malleus, the incus, and the stapes. From the stapes, the vibrations are transmitted to the cochlea. Receptors at the cochlea transduce (change) the vibrations into action potentials. The action potentials are conducted to the brain as nerve impulses by the cochlear portion of the eighth cranial (auditory) nerve. The nerve impulses are processed and interpreted as sound by the brain in the auditory cortex of the temporal lobe.

Ear and Hearing Changes Associated with Aging

Ear and hearing changes related to aging are listed in Chart 50-1, along with implications for care of older patients who have these changes. Some of the ear changes, such as an increase in ear size, are harmless. Other changes to ear structures may pose threats to the hearing ability of older adults.

All older adults should be screened for hearing acuity. Many scales or tools are available to assess hearing loss. However, asking “Do you have a hearing problem now?” may be just as helpful as these scales. Family members may have noticed behaviors that suggest changes in a patient’s hearing.

FIG. 50-4 Anatomic features and attached structures of the middle ear.

CHART 50-1 NURSING FOCUS ON THE OLDER ADULT

Age-Related Changes in the Ear and Hearing

EAR OR HEARING CHANGE	NURSING ADAPTATIONS AND ACTIONS
Pinna becomes elongated because of loss of subcutaneous tissues and decreased elasticity.	Reassure the patient that this is normal and does not indicate a problem. When positioning a patient on his or her side, take care not to “fold” the ear under the head.
Hair in the canal becomes coarser and longer, especially in men.	Reassure the patient that this is normal. The patient may require more frequent ear irrigation to keep cerumen from clumping in the hair.
Cerumen is drier and impacts more easily, reducing hearing function.	Teach the patient to irrigate the ear canal weekly or whenever he or she notices a change in hearing.
Tympanic membrane loses elasticity and may appear dull and retracted.	Do not use this finding as the only indication of otitis media.
Hearing acuity decreases (in some people).	Establish that a hearing deficiency exists, using simple, noninvasive tests such as the voice test and the watch test. If a deficit is present, refer the patient to an ear, nose, and throat specialist to determine what type of hearing loss is present and what can be done to improve hearing. Do not assume all older adults have a hearing loss!!
The ability to hear high-frequency sounds is lost first. Older adults may have particular problems hearing the <i>f</i> , <i>s</i> , <i>sh</i> , and <i>pa</i> sounds.	Provide a quiet environment when speaking (close the door to the hallway), and face the patient. If the patient wears glasses, be sure he or she is using them to see your lips and facial expression to enhance speech understanding. Speak slowly and in a deeper voice, and emphasize beginning word sounds. Some patients with a hearing loss that is not corrected may benefit from wearing a stethoscope while listening to you speak.

ASSESSMENT METHODS

Patient History

Obtain a thorough history from the patient before performing the physical examination. Hearing assessment begins while observing the patient listening to and answering questions. The patient's posture and appropriateness of responses provide information about hearing acuity. For example, posture changes, such as tilting the head to one side or leaning forward when listening to another person speak, may indicate the presence of a hearing problem. Other indicators of hearing difficulty include frequently asking the speaker to repeat statements or frequently saying “What?” or

CHART 50-2 EAR AND HEARING ASSESSMENT

Using Gordon's Functional Health Patterns

Cognitive-Perceptual Pattern

- Do you have any hearing difficulty?
- Do you use any type of hearing aid?
- Do you notice that you have the volume of the television or radio set at an increased level?
- Are you sitting closer to the television or radio to hear more clearly?
- Do you have difficulty in your ability to hear or follow conversations in a noisy environment, such as a restaurant?
- Do you have difficulty hearing high-pitched sounds like the doorbell?

Health Perception–Health Management Pattern

- Have you had your hearing checked?
- If you are or were exposed to environmental noise, have you consistently used appropriate hearing protection?
- Do you avoid cleaning your ear canals with foreign objects such as toothpicks or paper clips?
- Have you discussed with your health care provider the side effects of any drugs you may be taking that might affect your ear and hearing?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

“Huh?” Notice whether the patient responds to whispered questions and conversations and startles when an unexpected sound occurs in the environment. Also assess whether the patient's responses match the question asked. For example, when you ask the patient “How old are you?” does the patient respond with an age or does he or she say “No, I don't have a cold.”

During the interview, sit in adequate light and face the patient to allow him or her to see you speak. Use short, simple language the patient is comfortable with rather than long medical terms. Obtain data on demographics, personal and family history, socioeconomic status, current health problems, and the use of remedies for ear problems. [Chart 50-2](#) lists important questions to ask about functional hearing.

The patient's gender is important. Some hearing disorders, such as otosclerosis, are more common in women. Other disorders, such as Ménière's disease, are more common in men. Age is also an important factor in hearing loss.

Personal history includes past or current manifestations of ear pain, ear discharge, [vertigo](#) (spinning sensation), [tinnitus](#) (ringing), decreased hearing, and difficulty understanding people when they talk or difficulty hearing environmental noise. Ask the patient about:

- Ear trauma
- Ear surgery
- Past ear infections
- Excessive cerumen
- Ear itch
- Any invasive instruments routinely used to clean the ear (e.g., Q-Tip, match, bobby pin, key)
- Type and pattern of ear hygiene
- Exposure to loud noise or music
- Air travel (especially in unpressurized aircraft)
- Swimming and whether ear protection is used

- History of hereditary factors that can cause progressive hearing loss
- History of health problems that can decrease the blood supply to the ear such as heart disease, hypertension, or diabetes
- History of vitiligo (a pigment disorder in which there may be a loss of melanin-containing cells in the inner ear, resulting in hearing loss)
- History of smoking (reduces oxygenation of the cochlea)
- History of vitamin B₁₂ and folate deficiency (associated with age-related hearing loss)

If the patient uses foreign objects to clean the ear canal (e.g., bobby-pins, Q-tips, toothpicks, keys), explain the danger in using these objects. They can scrape the skin of the canal, push cerumen up against the eardrum, and even puncture the eardrum. If the patient says that cerumen buildup is a problem, teach him or her to use an ear irrigation syringe and proper solutions to remove it. [Chart 50-3](#) describes techniques to teach patients how to remove cerumen safely.

! NURSING SAFETY PRIORITY

Action Alert

Teach patients the safe way to clean their ears, stressing that nothing smaller than his or her own fingertip should be inserted into the canal.

If the patient uses a hearing aid, assess whether hearing is improved with its use. Obtain the date of the last hearing test, the type of test given, and the results. Ask about problems that may impair hearing such as allergies, upper respiratory infections, hypothyroidism, arteriosclerosis, head trauma, and recent head, facial, or dental surgery. A thorough drug history is important because many drugs are **ototoxic** (damaging to the ear) ([Table 50-1](#)).

Ask about the patient's occupation and hobbies that involve exposure to loud noise or music. Assess whether protective ear devices are used. Also ask whether any devices are consistently inserted into the ear, such as ear plugs or earpiece headsets, and for how long each day they are used. Use this opportunity to teach the patient about protecting his or her ears from loud noises by wearing protective ear devices, such as over-the-ear headsets or foam ear inserts, when persistent loud noises are in the environment. Also suggest the use of earplugs when engaging in water sports to prevent ear infections.

Assess the patient's socioeconomic status to determine the availability and affordability of health care. Some people might hesitate to have their hearing loss diagnosed because of the fear of needing to wear a hearing aid and the cost associated with these devices.

Family History and Genetic Risk

Family history, as well as personal history, is important in determining genetic risk for hearing loss. Although most genetic hearing loss is seen in childhood, some genetic problems can lead to progressive hearing loss in adults (Nussbaum et al., 2007). For example, most people with Down syndrome develop hearing loss as adults. People with osteogenesis imperfecta have bilateral and progressive hearing loss by their 30s.

CHART 50-3 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Self-Ear Irrigation for Cerumen Removal

- Do not attempt to remove ear wax or irrigate the ears if you have ear tubes or if you have blood, pus, or other drainage from the ear.
- Use an ear syringe designed for the purpose of wax removal. These are inexpensive, available at most drug stores, reusable, and can be used by more than one person when cleaned properly between uses.
- The safest type of ear syringe to use is one that has a right-angle or "elbow" in the tip.
- Irrigating your ears in the shower is an easy method.
- Always use tap water that feels just barely warm to you. If you are using a thermometer, keep the water temperature as close as possible to 98° or 99° F. Water that is warmer or colder can make you feel dizzy and nauseated.
- If your ear wax is thick and sticky, you may need to place a few drops of a warm ceruminolytic (commercial eardrops that soften ear wax) into the ear an hour or so before you irrigate the ear. Other substances that can be used for this purpose include baby oil or mineral oil.
- Fill the syringe with the lukewarm tap water.
- If you are using a syringe with an elbow tip, place only the last part of the tip into your ear and aim it toward the roof of your ear canal.
- If you are using a straight-tipped syringe, insert the tip only about $\frac{1}{2}$ - to $\frac{3}{4}$ -inch into your ear canal, aiming toward the roof of the canal.
- Hold your head at a 30-degree angle to the side you are irrigating.
- Use one hand to hold the syringe and the other to push the plunger or squeeze the bulb.
- Apply gentle but firm continuous pressure, allowing the water to flow against the top of the canal.
- Do not use blasts or bursts of sudden pressure.
- The ear canal should fill, and water will begin to flow out, bringing ear wax and debris with it.
- If a dental water-pressure irrigator is used, put it on the lowest possible setting.
- This process should not be painful! If pain occurs, decrease the pressure. If pain persists, stop the irrigation.
- Continue the irrigation until at least a cup of solution has washed into and out from your ear canal. (You may have to refill the syringe.)
- Tilting your head at a 90-degree angle to the side should allow most, if not all, of the water to drain out of your ear.
- Repeat the procedure on the other ear.
- If you feel that water is still in the canal, hold a hair dryer on a low setting near the ear.
- Irrigate your ears anytime from weekly to monthly, depending on how fast your ear wax collects.

GENETIC/GENOMIC CONSIDERATIONS

Mutations in several different genes are associated with hearing loss. One type of hearing loss among adults has a genetic basis with a mutation in gene *GJB2* on chromosome 1. This mutation causes poor production of the protein *connexin-26*, which has a role in the function of cochlear hair cells. Other genetic problems slow the metabolism and excretion of drugs, including ototoxic drugs. This allows ototoxic drugs to remain in the body longer, thus increasing the risk for hearing loss.

TABLE 50-1 OTOTOXIC DRUGS

DRUG TYPE	DRUG	DRUG TYPE	DRUG
Antibiotics	Amikacin	Nonsteroidal anti-inflammatory agents	Ibuprofen (Advil, Nuprin, Motrin)
	Capreomycin		Indomethacin (Indocin)
	Chloramphenicol		Naproxen (Aleve, Naprosyn, Anaprox)
	Dihydrostreptomycin		Piroxicam (Feldene), diflunisal (Dolobid), diclofene (Voltaren), etodolac (Lodine), nabumetone (Relafen), ketorolac (Toradol)
	Erythromycin		Salicylates (aspirin, Disalcid, Bufferin, Ecotrin, Trilisate, Ascriptin, Empirin, Excedrin, Fiorinal)
	Gentamicin (Garamycin, Cidomycin)		
	Kanamycin		
	Metronidazole (vestibulotoxicity rarely)		
	Neomycin		
	Netilmicin		
	Streptomycin		
	Tobramycin		
Diuretics	Acetazolamide (Apo-Acetazolamide 🍁, Diamox)	Chemotherapy agents	Actinomycin
	Ethacrynic acid (Edecrin)		Bleomycin
	Bumetanide		Cisplatin (Abiplatin, Platinol)
	Furosemide (Lasix, Apo-Furosemide 🍁, Furoside 🍁)		Carboplatin
			Nitrogen mustard (Mustargen)
			Vincristine
			Carbamazepine
			Hydroxychloroquine (Plaquenil)
		Miscellaneous	Quinine (Legatrin, Novo-Quinine 🍁, Quinamm)
			Quinidine (Apo-Quinidine 🍁, Cardioquin, Quinidex)

Ask the patient:

- Who in your family has hearing problems?
- Are the problems present in men and women equally or are they present more in one gender?
- At what age was hearing loss diagnosed in your relative(s)?
- Are both ears affected?

Current Health Problems

Assess current ear-related problems by asking the patient about any ear “trouble,” ear pain, or discharge, including earwax. Ask about any change in hearing, such as **hyperacusis** (the intolerance for sound levels that do not bother other people) or **tinnitus** (ringing in the ears). If a change in hearing is reported, ask whether one or both ears are involved and if the change was sudden or gradual. Also ask about problems with dizziness, sensations of being “off-balance,” or **vertigo** (sensation of spinning movement).

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

The client is a 28-year-old woman who reports to the nurse that she has experienced reduced hearing in both ears during the past 2 years. Which health issue or personal factor is most likely to be associated with the reduced hearing?

- Use of cotton-tipped applicators to clean the ears for her entire adult life.
- Use of oral contraceptives as the method of birth control for the past 3 years.
- Participation in a vegetarian diet that permits milk and eggs for the past 5 years.
- Management of chronic joint pain with daily naproxen (Aleve) for the past 3 years.

Physical Assessment

Inspection and palpation are used to assess the ear. Begin the examination by placing the patient in a sitting or supine position. Remove any hearing aids before the examination. Inspect the hearing aid for cracks, debris, and a proper fit. A complete ear examination is usually performed by a physician, advanced practice nurse, or physician assistant. The brief assessment of the ear and hearing usually performed by a medical-surgical nurse is described next.

External Ear and Mastoid Assessment

Inspect the entire external ear for shape, location of attachment to the head, and condition, including the condition of the visible external canal. The normal pinna is uniformly shaped without skin tags or deformity. The pinna should be attached to the side of the head at a posterior angle of 10 degrees or less. The normal external canal is dry, clean, free from lesions, and not reddened.

Abnormalities of the pinna include swelling, nodules, and lesions. In chronic gout, collections of uric acid crystals result in hard, irregular, painless nodules called **tophi** on the pinna. Other nodules on the pinna might also be from basal cell carcinoma or rheumatoid arthritis. Small, crusted, ulcerated, or indurated lesions on the pinna that fail to heal could be squamous cell carcinoma.

Inspect the mastoid process for redness and swelling, which indicate inflammation. To assess for tenderness, gently tap with one finger over the mastoid process, compress the tragus with one finger, and gently move the pinna forward and backward. Any tenderness suggests an inflammatory process in either the external ear or the mastoid.

Assess for and record these problems:

- Furuncles
- Large amounts of cerumen
- Scaliness

FIG. 50-5 Functional components of an otoscope.

- Redness
- Swelling of or drainage from the ear associated with a foreign object (insects or other substances), trauma, or infection
- Drainage such as blood, cerebrospinal fluid, pus, or serous fluid, and its character

Otoscopic Assessment

The purpose of a brief otoscopic examination is to assess the patency of the external canal, identify lesions or excessive cerumen in the canal, and assess whether the eardrum is intact or inflamed. An instrument called an **otoscope** is used to examine the ear. Many types are available. It consists of a light, a handle, a magnifying lens, and a pressure bulb for injecting air into the external canal to test mobility of the eardrum (Fig. 50-5). Specula of various diameters attach to the head of the otoscope. Select the largest speculum that most comfortably fits the patient's external canal.

! NURSING SAFETY PRIORITY

Action Alert

Do not use an otoscope to examine the ears of any patient who is unable to hold his or her head still during the examination.

If the patient has pain during the external ear examination, cautiously attempt an otoscopic examination. The speculum will cause extreme pain if it comes in contact with inflamed tissue in the external canal.

When performing an otoscopic examination, tilt the patient's head slightly away and hold the otoscope upside down, like a large pen (Fig. 50-6). This position permits your hand to lie against the patient's head for support. If the patient moves, both your hand and the otoscope also move, preventing damage to the external canal or eardrum. Hold the otoscope in your dominant hand, and gently pull the pinna up and back with your nondominant hand to straighten the canal. View the ear canal while you slowly insert the speculum. Use caution to avoid the pain associated with

FIG. 50-6 Proper technique for an otoscopic examination.

touching the speculum on the walls of the external canal. More experienced clinicians may use the down position during the otoscopic examination, with fingers placed on the patient's cheek for safety.

! NURSING SAFETY PRIORITY

Action Alert

Observe the ear canal through the otoscope as you insert the speculum into the external canal to avoid the risk for perforating the eardrum.

After the otoscope is comfortably introduced in the external canal, assess for lesions and the amount, consistency, and color of cerumen and hair. The normal external canal is skin colored, intact, and without lesions. It contains various amounts of soft cerumen and small, fine hairs.

Assess the eardrum for intactness and color. *The normal eardrum is always intact.* The eardrum is shiny, transparent, and opaque or pearly gray and without lesions. Redness is seen in otitis media. Reflection of the otoscope's light from the normal eardrum is the **light reflex**, and it appears as a clearly outlined triangle of light. The base of the triangle is on the annulus, and the point of the triangle is on the umbo. On the right eardrum, the light reflex appears in the right lower quadrant. On the left eardrum, the light reflex appears in the left lower quadrant. The light reflex is termed **diffuse** when the light reflex is spotty or multiple because of a changed eardrum shape from retraction or bulging.

! CULTURAL AWARENESS

Cerumen is generally moist and tan or brown in Euro-Americans and African Americans. It is dry and light brown to gray in Asians and American Indians. The distinction of dry or moist ear wax is a genetically inherited trait. The color of the lining of the external ear canal varies with the patient's skin tone. Variations should not be mistaken for indications of problems. Patients with more moist earwax may form cerumen impactions more easily than patients with drier, flaky earwax and require more frequent ear irrigations.

General Auditory Assessment

After assessing the external ear and the canals of both ears, briefly assess the patient's hearing acuity. Several rapid and simple tests for hearing can be performed at the patient's bedside. Although these tests do not determine the true extent or type of hearing loss, they can indicate a patient's functional hearing ability.

The *voice test* for hearing is a simple hearing acuity test that is conducted by asking the patient to block one external ear canal while standing 1 to 2 feet (30 to 60 cm) away. Quietly whisper a statement, and then ask the patient to repeat it. Test each ear separately. If the patient does not respond correctly, use a louder whisper. If you suspect the patient is lip-reading, use your hand to block the view of your mouth, or stand behind him or her while whispering.

The *watch test* for hearing is the use of a ticking watch to test acuity for high-frequency sounds. Hold a ticking watch about 5 inches (12.7 cm) from each ear and ask whether the ticking is heard. The patient with normal hearing should be able to hear it. If a watch that ticks cannot be found, test hearing by clicking the fingernails of your thumb and forefinger together about 12 inches from the patient's ear or just behind his or her head. More complex assessments of hearing, performed by audiologists, physicians, advanced practice nurses, specialty nurses, and physician assistants, can determine the type and extent of hearing loss.

Sound is transmitted by air conduction and bone conduction. Air conduction of sound is normally more sensitive than bone conduction. If hearing acuity is decreased, the hearing loss is categorized as:

- **Conductive hearing loss**, which results from physical obstruction of sound wave transmission such as a foreign body in the external canal, a retracted or bulging tympanic membrane, or fused bony ossicles.
- **Sensorineural hearing loss**, which results from a defect in the cochlea, the eighth cranial nerve, or the brain itself. Exposure to loud noise and music may cause this type of hearing loss as a result of damage to the cochlear hair cells.
- **Mixed conductive-sensorineural hearing loss**, which is a profound hearing loss resulting from both conductive and sensorineural hearing loss.

Each auditory function test determines the degree of hearing loss and differentiates the type of loss.

Audiology testing involves the use of a handheld device to generate tones of varying intensities to test hearing. Hearing can be measured at a 40-decibel (dB) intensity at frequencies of 500, 1000, 2000, and 4000 cycles per second (cps), or hertz (Hz). The audiometer is larger than a standard otoscope and is easily used to assess hearing.

Tuning fork tests for hearing acuity are the Weber and Rinne tests. These tests are useful, although limited, in distinguishing between conductive and sensorineural hearing losses. The frequency range of the tuning fork used for these tests corresponds to that of normal speech.

The Weber tuning fork test is performed by placing a vibrating tuning fork on the middle of the patient's head and asking him or her to indicate in which ear the sound is louder. The normal test result is sound heard equally in both ears. The term *lateralization* is used if the sound is louder in one ear. For example, lateralization to the right means that the sound is heard loudest in the right ear.

The Rinne tuning fork test compares hearing by air conduction with hearing by bone conduction. Sound is normally heard two to three times longer by air conduction than by bone conduction. The Rinne tuning fork test is performed by placing the vibrating tuning fork stem on the mastoid process (bone conduction) and asking the patient to indicate when the sound is no longer heard. When the patient no longer hears the sound, the fork is brought quickly in front of the pinna (air conduction) without touching the patient. He or she should then indicate when this sound is no longer heard. The patient normally continues to hear the sound two to three times longer in front of the pinna (air conduction) after not hearing it with the tuning fork touching the mastoid process (bone conduction).

Psychosocial Assessment

The patient may become irritable, frustrated, and depressed by an inability to hear and respond appropriately. The inability to hear often isolates the patient from the world. Depression may result from the sensory isolation of hearing loss. Be sensitive to the patient, and conduct the interview at a pace appropriate for that person.

Ask about social and work relationships to determine whether the patient is isolated because of hearing problems. In addition, encourage the patient to express feelings related to hearing loss and discuss any changes in daily living activities that have been made as a result of a change in hearing. Also obtain information from family members, especially if the patient does not acknowledge having a hearing problem.

DECISION-MAKING CHALLENGE

Safety

You are admitting a 78-year-old man to a rehabilitation and long-term care facility on discharge from the hospital after a transurethral resection prostatectomy. He is not very steady on his feet and is still dribbling urine. The hand-off report indicates that he did not seem to understand his care instructions although his family states he has no cognitive, vision, or hearing problems. When you tell the patient your name (Terry), he repeats it as "Mary." When you repeat your name a little louder, he says "Just quit mumbling and shouting. I have perfect hearing."

1. Should you apologize for this misunderstanding? Why or why not?
2. You plan to make a hearing assessment as part of your admission assessment. How should you introduce this assessment to the patient after his statement of having perfect hearing?
3. What types of issues could be affecting his hearing?

Diagnostic Assessment

Laboratory Assessment

Laboratory tests generally are not of value in determining hearing acuity. For an external ear infection, the typical causative organisms are known and this infection is treated without obtaining cultures. If the usual antibiotic therapy is not successful at clearing the infection, microbial culture and antibiotic sensitivity tests may be performed.

Imaging Assessment

Computed tomography (CT), with or without contrast enhancement, shows the structures of the ear in great detail by multiple x-ray scans of the head. These scans are then averaged by a computer. CT is especially helpful in diagnosing acoustic tumors.

Magnetic resonance imaging (MRI) is a noninvasive, non-radioactive diagnostic tool that uses a computer to generate images. Because of its superior contrast resolution, bones do not obscure the tissue image, so the MRI most accurately reflects soft-tissue changes. Patients with older internal metal vascular clips cannot have MRI. Newer clips are made from titanium and are not a contraindication for MRI.

Specific Auditory Assessment

Audiometry. Audiometry is the measurement of hearing acuity. It is performed by audiologists, audiology technicians, or nurses with special training. **Frequency** is the highness or lowness of tones (expressed in hertz). The greater the number of vibrations per second, the higher the frequency (pitch) of the sound. The fewer the number of vibrations per second, the lower the frequency (pitch).

Intensity of sound is expressed in decibels (dB). **Threshold** is the lowest level of intensity at which pure tones and speech are heard by a patient about 50% of the time.

The lowest intensity at which a young, normal ear can detect sound about 50% of the time is 0 dB. Sound at 110 dB is so intense (loud) that it is painful for most people with normal hearing. Conversational speech is around 60 dB, and a soft whisper is around 20 dB (Table 50-2). A hearing loss of 45 to 50 dB renders the person unable to hear speech without a hearing aid. A person with a hearing loss of 90 dB may not be able to hear speech even with a hearing aid.

Pure tones are generated by an audiometer to determine hearing acuity. The two types of audiometry are pure-tone audiometry and speech audiometry.

Pure-Tone Audiometry. Pure-tone audiometry generates tones with an audiometer that are presented to the patient at frequencies for hearing speech, music, and other common sounds. It can be performed by air-conduction testing or bone-conduction testing. The results of pure-tone audiometry are graphed on an audiogram. The hearing of one ear may be masked while the hearing of the other ear is tested.

Pure-tone air-conduction testing determines whether a patient hears normally or has a hearing loss. It is designed to

test air-conduction hearing sensitivity (through earphones) at frequencies ranging from 125 to 8000 Hz. Thresholds are usually confined to the frequencies of 250, 500, 1000, 2000, 4000, and 8000 Hz. The intensities for pure tones generally range from 10 to 110 dB.

The patient sits in a sound-isolated room to reduce background noise. Earphones are placed over the ears, and tones of varying frequencies and intensities are delivered through the earphones, testing one ear at a time. The patient presses a button or raises a hand to indicate when he or she hears a tone. No special follow-up care is needed.

Pure-tone bone-conduction testing determines whether the hearing loss detected by air-conduction testing is due to conductive or sensorineural factors or to a combination of the two. It is used only when the results of air-conduction testing are abnormal. Testing is similar to air-conduction testing except that a bone-conduction vibrator, placed firmly behind the pinna on the mastoid process, is used instead of earphones. No special follow-up care is needed.

Interpretation of audiometric evaluation determines whether the patient's hearing is within normal limits or, with a hearing impairment, whether the hearing loss is conductive, sensorineural, or mixed. The type of loss can be determined by an experienced clinician who examines the shape of the audiogram after completion of pure-tone air- and bone-conduction audiometry.

Speech Audiometry. In speech audiometry, the patient's ability to hear spoken words is measured through a microphone connected to an audiometer. The two components of speech audiometry are the speech reception threshold and speech discrimination.

Speech reception threshold is the minimum loudness at which a patient can repeat simple words. This test determines how loud a simple speech stimulus must be before the patient can hear it well enough to repeat it correctly. In one common test, lists of two-syllable words called **spondee** are used (i.e., words in which there is generally equal stress on each syllable, such as *airplane*, *railroad*, and *cowboy*).

The speech reception threshold measured by the audiometer is the hearing level at which the patient can repeat simple words correctly 50% of the time. The test is conducted in a manner similar to the pure-tone tests.

Speech discrimination testing determines the patient's ability to discriminate among similar sounds or among words that contain similar sounds. The ability to understand speech is the most important measurable aspect of human hearing. Speech discrimination testing assesses *understanding* of speech. A hearing loss may decrease sensitivity to sound and impair understanding of what is being said.

A standard format contains lists of 25 to 50 **monosyllabic** (one-syllable) words, such as *carve*, *day*, *toe*, and *ran*, and phonemically balanced words, with equal word difficulty between lists. The lists are presented to the patient through earphones at a selected loudness level, generally about 30 to 40 dB above the speech reception threshold, or at the patient's most comfortable listening level. A percentage score is derived from the number of words repeated correctly.

Tympanometry. Tympanometry assesses mobility of the eardrum and structures of the middle ear by systematically changing air pressure in the external auditory canal. The progression or resolution of serous otitis and otitis media can be accurately monitored with this procedure.

TABLE 50-2 DECIBEL INTENSITY AND SAFE EXPOSURE TIME FOR COMMON SOUNDS

SOUND	DECIBEL INTENSITY (DB)	SAFE EXPOSURE TIME*
Threshold of hearing	0	
Whispering	20	
Average residence or office	40	
Conversational speech	60	
Car traffic	70	>8 hr
Motorcycle	90	8 hr
Chain saw	100	2 hr
Rock concert, front row	120	3 min
Jet engine	140	Immediate danger
Rocket launching pad	180	Immediate danger

*For every 5-dB increase in intensity, the safe exposure time is cut in half.

This test is helpful in distinguishing middle ear pathologic conditions, such as otosclerosis, ossicular disarticulation, otitis media, and perforation of the eardrum. It is also useful for assessing patency of the eustachian tube and for checking recovery of middle ear function after surgery.

Auditory Brainstem-Evoked Response. Auditory brainstem-evoked response (ABR) assesses hearing in patients who are unable to indicate their recognition of sound stimuli during standard hearing tests. This test helps diagnose both conductive and sensorineural hearing losses. Electrodes are placed on the scalp during the test. After the test, clean the patient's hair to remove the electrode gel.

To prepare the patient for ABR:

- Tell the patient that no fasting or sedation is needed
- Carefully explain the procedure and its purpose
- Inform the patient that the procedure usually takes about 30 minutes

Assessment of Balance

Electronystagmography (ENG) is a test that is sensitive in detecting both central and peripheral disease of the vestibular system in the ear. The ENG detects and records **nystagmus** (involuntary eye movements) because the eyes and ears depend on each other for balance. Electrodes are taped to the skin near the eyes, and one or more procedures (caloric testing, changing gaze position, or changing head position) are performed to stimulate nystagmus. Failure of nystagmus to occur with cerebral stimulation suggests an abnormality in the vestibulocochlear apparatus, the cerebral cortex, the auditory nerve, or the brainstem.

To prepare the patient for ENG:

- Carefully explain the procedure and its purpose. The examiners will be asking the patient to name names or do simple math problems during the test to ensure he or she stays alert.
- Tell the patient to fast for several hours before the test and to avoid caffeine-containing beverages for 24 to 48 hours before the test.
- Tell patients with pacemakers that they should not have the test because pacemaker signals interfere with the sensitivity of ENG.

- Carefully introduce oral fluids after the test to prevent nausea and vomiting.

Caloric testing evaluates the vestibular (inner ear) portion of the auditory nerve. Warm water or warm air is infused into the ear. A normal response is the onset of vertigo and nystagmus within 20 to 30 seconds. Prepare the patient for caloric testing by:

- Carefully explaining the procedure and its purpose.
- Telling the patient to fast for several hours before the test.
- Telling the patient that the affected side will be tested first.
- Explaining that he or she will be on bedrest after the procedure with careful introduction of oral fluids to prevent nausea and vomiting.

Dix-Hallpike testing for vertigo is performed by assisting the patient to a sitting position on an examination table. Stand to the side of the patient, and quickly reposition him or her from sitting to supine with the head extending beyond the end of the table. This change of position is done first to one side and then to the other side. A patient with benign positional vertigo will have a burst of nystagmus after a delay of 5 to 10 seconds.

To prepare the patient for the Dix-Hallpike test:

- Carefully explain the procedure and its purpose.
- Tell him or her to keep the eyes open and try not to blink.
- Explain that double vision may occur during the test.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which precaution or action is the priority for the nurse to teach the client who is scheduled to undergo tympanometry, pure-tone audiometry, and caloric testing?

- Avoid aspirin and aspirin-containing products for 1 week before testing.
- Shower and wash your hair the night before testing.
- Do not eat or drink within 4 hours before testing.
- Do not smoke for 24 hours before the testing.

NURSING CONCEPT REVIEW

What should you expect to NOTICE in a patient with adequate sensation related to the ear and hearing?

- Ears are symmetric on the face on a line about even with the corners of the eyes and with the tops of the ears rotated slightly toward back.
- Outer ear (pinna) has no open areas, scales, or bumps.
- No drainage occurs from the ear canal.
- Does not tilt one side of the head or lean forward when listening to another person speak.
- Startles when a loud or unexpected sound occurs in the environment.

- Responds appropriately to questions.
- Does not consistently ask a speaker to repeat himself or herself; does not say “What?” or “Huh?” frequently.
- Responds appropriately to greetings with other people in the immediate environment.
- Responds appropriately to whispered questions and conversations, even when the speaker is not facing the patient.

GET READY FOR THE NCLEX® EXAMINATION!**KEY POINTS**

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use a separate speculum cover for each ear when conducting an otoscopic examination.
- Slowly and gently introduce the otoscopic speculum into the external ear canal during assessment.
- Use Standard Precautions with any patient who has drainage from the ear canal.
- Do not perform an otoscopic examination on a confused patient.
- Use the suggestions presented in the Patient History section to enhance communication with a patient who has a hearing impairment.

Health Promotion and Maintenance

- Teach patients the proper way to clean the pinna and external ear canal.

- Identify patients at risk for hearing impairment as a result of work environment or leisure activities.
- Encourage all patients, even if they already have a hearing impairment, to use ear protection in loud environments.
- Inform all patients who smoke that smoking increases the risk for development of hearing problems.

Psychosocial Integrity

- Allow the patient the opportunity to express fear or anxiety about a change in hearing status.
- Explain all diagnostic procedures, restrictions, and follow-up care to the patient scheduled for tests.

Physiological Integrity

- Ask the patient about hearing problems in any other members of the family, because many hearing problems have a genetic component.
- Ask the patient whether he or she has ever used any ototoxic drugs (see [Table 50-1](#)).

Care of Patients with Ear and Hearing Problems

Key Points

Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Apply principles of infection control when examining an ear with drainage.
2. Implement precautions to prevent falls in patients experiencing vertigo or dizziness.
3. Correctly instill eardrops.

Health Promotion and Maintenance

4. Teach patients using hearing aids how to use and care for them properly.

Psychosocial Integrity

5. Teach patients and family members about what to expect during tests, procedures, and follow-up to manage ear and hearing problems.
6. Provide opportunities for the patient and family to express feelings and concerns about a change in hearing.

7. Refer hearing-impaired patients and families to local and Internet-based support services.

Physiological Integrity

8. Compare the clinical manifestations and interventions for external otitis with those of otitis media.
9. Safely remove impacted cerumen from the ear canal of an older patient.
10. Coordinate the care of the patient with Ménière's disease.
11. Prioritize nursing care needs for the patient after tympanoplasty.
12. Prioritize educational needs for the patient after stapedectomy.
13. Identify an appropriate method for communicating with a patient who has recently become hearing impaired.

The ears are important for hearing and balance. Ear disorders may lead to hearing difficulty, balance problems, and impaired general function. Hearing problems reduce the ability of patients to fully communicate with the world around them. They can lead to confusion, mistrust, social isolation, and the inability to give and receive accurate information. Although ear and hearing disorders are often easily managed, early recognition and intervention are necessary to prevent additional damage and to promote a maximum level of wellness.

CONDITIONS AFFECTING THE EXTERNAL EAR

The external ear is the outermost part of the ear structures and is subject to outside factors that can cause problems. Disorders of the external ear include congenital malformation (birth defects), trauma, and infectious or noninfectious lesions of the pinna, auricle, or auditory canal. The presence of birth defects in one area does not necessarily mean that other areas of the ear also will be affected. Abnormalities of

the external ear range from crumpling or falling forward of the pinna to complete absence (**atresia**) of the auditory canal. Trauma can damage or destroy the auricle and external canal. Surgical reconstruction can re-form the pinna with skin grafts and plastic prostheses. Trauma to the auricle resulting in a hematoma requires the removal of blood via needle aspiration to prevent calcification and hardening, which is often referred to as a **cauliflower** or **boxer's ear**.

Benign cysts or polyps of the auricle or external canal are surgically removed if they block the canal and affect hearing. Cancer cells, usually basal cell carcinoma, can occur on the pinna. Usually, treatment consists of simple excision. When the lesion becomes larger, its location near the skull and facial nerve makes treatment more difficult.

EXTERNAL OTITIS

Pathophysiology

External otitis is a painful condition caused when irritating or infective agents come into contact with the skin of the external ear. The result is either an allergic response or inflammation with or without infection. Affected skin becomes red, swollen, and tender to touch or movement. Swelling of the ear canal can lead to temporary hearing loss due to obstruction. Allergic external otitis is often caused by contact with cosmetics, hair sprays, earphones, earrings, or hearing aids. The most common infectious organisms are *Pseudomonas aeruginosa*, *Streptococcus*, *Staphylococcus*, and *Aspergillus*.

External otitis occurs more often in hot, humid environments, especially in the summer, and is known as **swimmer's ear** because it occurs most often in people involved in water sports. Patients who have traumatized their external ear canal with sharp or small objects (e.g., hairpins, cotton-tipped applicators) or with headphones also are more susceptible to external otitis.

Necrotizing or malignant otitis is the most virulent form of external otitis. Organisms spread beyond the external ear canal into the ear and skull. The high mortality rate seen with malignant external otitis results from complications such as meningitis, brain abscess, and destruction of cranial nerve VII.

PATIENT-CENTERED COLLABORATIVE CARE

Manifestations of external otitis range from mild itching to pain with movement of the pinna or tragus, particularly when upward pressure is applied to the external canal. Patients report feeling as if the ear is plugged and hearing is reduced.

Use caution during otoscopic examination to avoid pressing on the walls of the external canal, which causes pain. Drainage from the ear is often greenish white. To prevent cross-contamination, examine the unaffected ear first. Hearing loss in the affected ear can be severe when inflammation obstructs the ear canal and prevents sounds from reaching the eardrum (**tympanic membrane**).

Management focuses on reducing inflammation, edema, and pain. Nursing priorities include comfort measures, such as applying heat to the ear for 20 minutes three times a day. This can be accomplished by using towels warmed with water and then wrapped in a plastic bag or by using a heating pad placed on a low setting. Teach the patient that minimizing head movements reduces pain.

CHART 51-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Instillation of Eardrops

- Gather the solutions to be administered.
- Check the labels to ensure correct dosage and time.
- Wear gloves to remove and discard any ear packing.
- Wash your hands.
- Perform a gentle otoscopic examination to determine whether the eardrum is intact.
- Irrigate the ear if the eardrum is intact (see [Chart 51-2](#)).
- Place the bottle of eardrops (with the top on tightly) in a bowl of warm water for 5 minutes.
- Tilt the patient's head in the opposite direction of the affected ear, and place the drops in the ear.
- With his or her head tilted, ask the patient to gently move the head back and forth five times.
- Insert a cotton ball into the opening of the ear canal to act as packing.
- Wash your hands again.

FIG. 51-1 Earwick for instillation of antibiotics into the external canal. When edema occludes the external auditory canal, it is difficult for antibiotic solutions to enter the canal adequately. An earwick is placed through the meatus. Solutions placed on the external portion of the earwick are absorbed through the canal.

Topical antibiotic and steroid therapies are most effective in decreasing inflammation and pain. Review best practices for instilling eardrops with the patient, as shown in [Chart 51-1](#). Observe the patient self-administer the eardrops to make sure that proper technique is used. If edema obstructs the external canal, an earwick is inserted past the blockage, with drugs applied to the outside end ([Fig. 51-1](#)). A long piece of gauze dressing serves as an earwick, which the health care provider inserts using forceps to push carefully through the blocked external auditory canal to the eardrum. The earwick may be removed when eardrops can flow freely into the canal. Use handwashing whenever the infected ear is touched. Oral or IV antibiotics are used in severe cases, especially when infection spreads to surrounding tissue or area lymph nodes are enlarged.

Analgesics, including opioids, may be needed for pain relief during the initial days of treatment. NSAIDs, such as acetylsalicylic acid (aspirin, Entrophen ) and ibuprofen (Advil), or acetaminophen (Tylenol, Abenol ) may relieve less-severe pain.

After the inflammation has subsided, a solution of 50% rubbing alcohol, 25% white vinegar, and 25% distilled water may be dropped into the ear to keep it clean and dry and to prevent recurrence. Teach the patient not to use cotton-tipped applicators to dry the ears, because this use could damage the canal and increase the risk for infection or inflammation. Teach him or her to use preventive measures for minimizing ear canal moisture, trauma, or exposure to materials that lead to local irritation or contact dermatitis. Recommend the use of earplugs when engaging in water sports to those patients with recurrent episodes of external otitis.

NCLEX EXAMINATION CHALLENGE

Psychosocial Integrity

The client with external otitis reports reduced hearing in the affected ear and asks whether the hearing loss will be permanent. What is the nurse's best response?

- A. "Yes, but fortunately the hearing of the other ear remains normal."
- B. "Yes, but this type of problem can be helped with a hearing aid."
- C. "No, infection does not lead to any type of permanent hearing loss."
- D. "No, if the infection does not reach the middle ear, hearing will return."

FURUNCLE

A **furuncle** is a localized external otitis caused by bacterial infection, usually *Staphylococcus*, of a hair follicle. Most furuncles occur on the outer half of the external canal.

The manifestations of a furuncle include intense local pain to light touch. The area is swollen and red, with tight skin covering the area, possibly with a purulent head. No drainage is seen unless the furuncle has ruptured. Hearing is impaired if the lesion blocks the canal.

Treatment consists of local and systemic antibiotics and local heat application. An earwick may be used with one-half strength Burow's solution to relieve pain. The furuncle may need to be incised and drained if it does not resolve with antibiotic therapy.

PERICHONDritis

Perichondritis is an infection of the **perichondrium**, a tough, fibrous tissue layer that surrounds the cartilage and shapes the pinna. This tissue supplies blood to the ear cartilage. Infection can be caused by opening an area of pus or localized infection, insect bites, trauma, postoperative complication of tympanoplasty, and cartilage ear piercing. When infection occurs between the perichondrium and the cartilage, blood flow to the cartilage can be reduced to the point that necrosis occurs and the pinna may become deformed. This can occur as a complication of high helical ear piercing and may require removal of necrotic tissue.

The purposes of management are to eliminate the infection and ensure that the perichondrium stays in direct contact

FIG. 51-2 Irrigation of the external canal. Cerumen and debris can be removed from the ear by irrigation with warm water. The stream of water is aimed above or below the impaction to allow back-pressure to push it out rather than further down the canal.

with the cartilage. In addition to systemic antibiotic therapy, a wide incision is made and suction drainage is used to remove pus and other fluid.

CERUMEN OR FOREIGN BODIES

Pathophysiology

Cerumen (wax) is the most common cause of an impacted canal. A canal can also become impacted as a result of foreign bodies that can enter or be placed in the external ear canal, such as vegetables, beads, pencil erasers, and insects. Although uncomfortable, cerumen or foreign bodies are rarely true emergencies and can be carefully removed by a health care professional. Cerumen impaction in the older adult is common, and removal of the cerumen from older adults often improves hearing (Holcomb, 2009).

PATIENT-CENTERED COLLABORATIVE CARE

Patients with a cerumen impaction or a foreign body in the ear may experience a sensation of fullness in the ear, with or without hearing loss, and may have ear pain, itching, dizziness, or bleeding from the ear. The object may be visible with direct inspection.

When the occluding material is cerumen, management options include watchful waiting, manual removal, and the use of ceruminolytic agents followed by either manual irrigation or the use of a low-pressure, electronic, oral irrigation device (Holcomb, 2009). The canal can be irrigated with a mixture of water and hydrogen peroxide at body temperature (Fig. 51-2), following best practices for proper irrigation (Chart 51-2). Removal of a cerumen obstruction by irrigation is a slow process and may take more than one sitting. When it is the cause of hearing loss, cerumen removal may improve hearing. Between 50 and 70 mL of solution is the maximum

CHART 51-2 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE**Ear Irrigation**

- Wash your hands.
- Use an otoscope to check the location of the impacted cerumen; ascertain that the eardrum is intact and that the patient does not have otitis media.
- Gather the proper equipment: basin, syringe (without needle), otoscope, towel.
- Warm tap water (or other prescribed solution) to body temperature.
- Fill a syringe with the warmed irrigating solution.
- Place a towel around the patient's neck.
- Place a basin under the ear to be irrigated.
- Place the tip of the syringe at an angle so that the fluid pushes on one side of and not directly on the impaction (this helps loosen the impaction instead of forcing it further into the canal).
- Apply gentle but firm continuous pressure, allowing the water to flow against the top of the canal.
- Do not use blasts or bursts of sudden pressure.
- If pain occurs, decrease the pressure. If pain persists, stop the irrigation.
- Watch the fluid return for signs of cerumen plug removal.
- Continue to irrigate the ear with about 70 mL of fluid.
- If the cerumen does not drain out, wait 10 minutes and repeat the irrigation procedure.
- Monitor the patient for signs of nausea.
- If the patient becomes nauseated, stop the procedure.
- If the cerumen cannot be removed by irrigation, place (or the patient may place) mineral oil into the ear three times a day for 2 days to soften dry, impacted cerumen, after which irrigation may be repeated.
- After completion of the irrigation, have the patient turn his or her head to the side just irrigated to drain any remaining irrigation fluid.
- Wash your hands.

amount that the patient with an impaction usually can tolerate at one sitting.

! NURSING SAFETY PRIORITY**Action Alert**

Do not irrigate an ear with an eardrum perforation or otitis media because this may spread the infection to the inner ear. Also, do not irrigate the ear when the foreign object is vegetable matter, because this material expands when wet, making the impaction worse. For vegetable matter, the object needs to be physically removed by an experienced health care professional.

If the cerumen is thick and dry or cannot be removed easily, suggest an over-the-counter ceruminolytic product such as Cerumenex to soften the wax before trying to remove it. Another way to soften cerumen is to add 3 drops of glycerin or mineral oil to the ear at bedtime and 3 drops of hydrogen peroxide twice a day. After several days of this treatment, the cerumen is more easily removed by irrigation. In some cases, a small curette or cerumen spoon may be used by a health care professional to scoop out the wax. Care is taken with this method because damage to the canal or the eardrum can occur with improper technique.

Discourage the use of cotton swabs and ear candles (hollow tubes coated in wax inserted into the ear and then lighted at

CHART 51-3 NURSING FOCUS ON THE OLDER ADULT**Cerumen Impaction**

- Assess the hearing of all older patients using simple voice tests (see Chapter 50).
- Perform a gentle otoscopic inspection of the external canal and eardrum of any older patient who has a problem with hearing acuity, especially the patient who wears a hearing aid.
- Use ear irrigation to remove any impacted cerumen.
- Make certain that the irrigating fluid is about 98.6° F (37° C) to reduce the chance for stimulating the vestibular sense.
- Use no more than 5 to 10 mL of irrigating fluid at a time.
- If nausea, vomiting, or dizziness develops, stop the irrigation immediately.
- Teach the patient how to irrigate his or her own ears.
- Obtain a return demonstration of ear irrigation from the patient, observing for specific areas in which the patient may need assistance.
- Encourage the patient to wash the external ears daily using a soapy, wet washcloth over the index finger (best done in the shower or while washing the hair).

the far end) to clean the ears or remove cerumen. Chart 50-3 in Chapter 50 describes steps to teach patients regarding ear hygiene and self-ear irrigation. Refer to Chart 51-3 for nursing care considerations of older adult patients with cerumen impaction.

Insects are killed before removal unless they can be coaxed out by a flashlight or a humming noise. Lidocaine, a numbing agent, can be placed in the ear canal for pain relief. Mineral oil or diluted alcohol instilled into the ear can suffocate the insect, which is then removed with ear forceps.

If the patient has local irritation, an antibiotic or steroid ointment may be applied to prevent infection and reduce local irritation. Hearing acuity is tested if hearing loss is not resolved by removal of the object.

Surgical removal of the foreign object may be required. The object is removed through the ear canal (transcanal route) using a wire bent at a 90-degree angle. The wire is looped around the object, and the object is pulled out.

**DECISION-MAKING CHALLENGE****Safety; Patient-Centered Care**

A 78-year-old woman who is an assisted-living resident reports pain in and drainage from her right ear. She also reports decreased hearing in the affected ear. When you examine her, she asks if she can just have some medicine without an examination of the ear. You reassure her that you will be gentle and not cause more pain. She reluctantly agrees to be examined.

1. Describe exactly how you would proceed with this ear assessment.
2. What other vital signs should you take and why?
As you prepare to perform an otoscopic examination of the right ear, the patient tells you that last week her ear itched and that she used a pencil to scratch the ear canal. When she removed the pencil, the eraser was missing. Her ear pain and discharge began about 3 days later.
3. Should you proceed with an otoscopic examination now? Why or why not?
4. What type of problem do you suspect with this situation?

Because this procedure is painful, general anesthesia is needed.

CONDITIONS AFFECTING THE MIDDLE EAR

OTITIS MEDIA

Pathophysiology

The three common forms of otitis media are acute otitis media, chronic otitis media, and serous otitis media. Each type affects the middle ear but has different causes and pathologic changes. If otitis progresses or is untreated, permanent conductive hearing loss may occur.

Acute otitis media and chronic otitis media, also known as *suppurant* or *purulent* otitis media, are similar. An infecting agent in the middle ear causes inflammation of the mucosa, leading to swelling and irritation of the small bones (*ossicles*) within the middle ear, followed by purulent inflammatory exudate. Acute disease has a sudden onset and lasts 3 weeks or less. Chronic otitis media often follows repeated acute episodes, has a longer duration, and causes greater middle ear injury. It may be a result of the continuing presence of a biofilm in the middle ear. A biofilm is a community of bacteria working together to overcome host defense mechanisms to continue to survive and proliferate (Lee et al., 2009). (See Chapter 25 for more information about biofilms.) Therapy for complications associated with chronic otitis media, unlike that of acute otitis media, usually involves surgical intervention.

The eustachian tube and mastoid, connected to the middle ear by a sheet of cells, are also affected by the infection. If the eardrum membrane perforates and infective materials spill into the external ear, external otitis develops that thickens and scars the middle ear if left untreated. Necrosis of the ossicles destroys middle ear structures and causes hearing loss.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The patient with acute or chronic otitis media has ear pain with and without movement of the external ear. Acute otitis media causes more intense pain. As the pressure in the middle ear increases, there is a sensation of fullness in the ear. Hearing is reduced and distorted. The patient may notice a sticking or cracking sound in the ear upon yawning or swallowing or may have tinnitus in the form of a low hum or a low-pitched sound. Conductive hearing loss may occur as sound wave transmission is obstructed. Headaches and systemic symptoms such as malaise, fever, nausea, and vomiting can occur. As the pressure on the middle ear pushes against the inner ear, the patient may have dizziness or vertigo.

Otoscopic examination findings vary, depending on the stage of the condition. The eardrum is initially retracted, which allows landmarks of the ear to be seen clearly. At this early stage, the patient has only vague ear discomfort. As the condition progresses, the eardrum's blood vessels dilate and appear red (Fig. 51-3). In the third stage, the eardrum becomes red, thickened, and bulging, with loss of landmarks. Decreased eardrum mobility is evident on inspection with a pneumatic otoscope. Pus may be seen behind the membrane.

FIG. 51-3 Otoscopic view of otitis media.

FIG. 51-4 Otoscopic view of a perforated tympanic membrane.

If the condition progresses, the eardrum spontaneously **perforates** (ruptures) and pus or blood drains from the ear (Fig. 51-4). When the membrane ruptures, the patient notices a marked decrease in pain as the pressure on middle ear structures is relieved (Fig. 51-5). Eardrum perforations from any cause may heal if the underlying problem is controlled. Initially, the eardrum membrane is thinner over the healed perforation. A simple central perforation does not interfere with hearing unless the small bones of the middle ear are damaged or the perforation is large. Repeated perforations with extensive scarring can cause hearing loss.

Cultures of drainage after a perforation from uncontrolled otitis media may reveal the infecting agent. Cultures are taken only when previous treatment is ineffective. When the eardrum is not perforated, a needle aspiration or myringotomy may be performed by a physician or nurse practitioner to withdraw fluid for culture.

INTERVENTIONS

Nonsurgical Management

Management can be as simple as putting the patient in a quiet environment. Bedrest limits head movements that intensify the pain. Heat may be applied by using a heating pad adjusted to a low setting. Application of cold also may relieve pain.

Topical antibiotics are not used to treat otitis media. Systemic antibiotic therapy decreases pain by reducing inflammation. Teach the patient to complete the antibiotic therapy as prescribed and to not stop taking the drug when manifestations are no longer present. Stopping the drug early may

FIG. 51-5 Perforations of the tympanic membrane. Central perforations heal more quickly than marginal perforations. Marginal perforations that do not heal allow cholesteatoma formation.

result in infection recurrence and contributes to antibiotic resistance. Analgesics such as aspirin, ibuprofen (Advil), and acetaminophen (Tylenol, Abenol ) relieve pain and reduce fever, helping the patient feel better. When pain is severe, opioid analgesics such as codeine also may be prescribed.

Antihistamines and decongestants are prescribed to decrease fluid in the middle ear. The body can then reabsorb the fluid, reducing pressure and pain.

Surgical Management

If pain persists after antibiotic therapy and the eardrum continues to bulge, a **myringotomy** (surgical opening of the pars tensa of the eardrum) is performed. This procedure drains middle ear fluids and immediately relieves pain.

Preoperative care includes reassuring the patient that the myringotomy will relieve pain and is usually performed

FIG. 51-6 Grommet through the tympanic membrane. A small grommet is placed through the tympanic membrane away from the margins, which allows prolonged drainage of fluids from the middle ear. The grommet can be removed later and the tympanic membrane allowed to heal naturally or patched with a small piece of homogenous tissue.

without anesthesia. Many people are concerned about a perforation and its effect on hearing. To relieve some of this anxiety, discuss the reasons for the procedure and encourage the patient to use techniques such as deep breathing before and during the procedure. Systemic antibiotic therapy continues before and after this procedure. Clean the external canal with a bacteriostatic solution such as povidone-iodine (Betadine) before the myringotomy.

The operative procedure is a small surgical incision often performed in an office or clinic setting and heals rapidly. Another approach is the removal of fluid from the middle ear with a needle. For relief of pressure caused by serous otitis media and for those patients who have repeated episodes of otitis media, a small **grommet** (polyethylene tube) may be surgically placed through the eardrum to allow continuous drainage of middle ear fluids (Fig. 51-6).

Postoperative care priorities include teaching the patient to keep the external ear and canal free of other substances while the incision is healing. Instruct him or her to keep the head dry by not washing the hair or showering for several days. Other instructions after surgery are listed in [Chart 51-4](#).

MASTOIDITIS

Pathophysiology

The lining of the middle ear is continuous with the lining of the mastoid air cells, which are embedded in the temporal bone. **Mastoiditis** is an infection of the mastoid air cells caused by untreated or inadequately treated otitis media. This infection can be acute or chronic. Antibiotic therapy is used to treat the middle ear infection before it progresses to mastoiditis.

CHART 51-4 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Recovery from Ear Surgery

- Avoid straining when you have a bowel movement.
- Do not drink through a straw for 2 to 3 weeks.
- Avoid air travel for 2 to 3 weeks.
- Avoid excessive coughing for 2 to 3 weeks.
- Stay away from people with respiratory infections.
- If you need to blow your nose, blow gently, without occluding either nostril, with your mouth open.
- Avoid getting your head wet, washing your hair, and showering for 1 week.
- Keep your ear dry for 6 weeks by placing a ball of cotton coated with petroleum jelly (e.g., Vaseline) in your ear. Change the cotton ball daily.
- Avoid rapidly moving the head, bouncing, and bending over for 3 weeks.
- Change your ear dressing every 24 hours or as directed.
- Report excessive drainage immediately to your physician.

PATIENT-CENTERED COLLABORATIVE CARE

The manifestations of mastoiditis include swelling behind the ear and pain with minimal movement of the tragus, the pinna, or the head. Pain is *not* relieved by myringotomy. **Cel-lulitis** (infection spreading sideways through the tissues of the skin) develops on the skin or external scalp over the mastoid process. The ear is pushed sideways and down. Otoscopic examination shows a red, dull, thick, immobile eardrum with or without perforation. Lymph nodes behind the ear are tender and enlarged. Patients may have low-grade fever, malaise, ear drainage, and loss of appetite. Hearing loss occurs, and computed tomography (CT) scans show fluid in the air cells of the mastoid process.

Interventions focus on halting the infection before it spreads to other structures. IV antibiotics are used to prevent the spread of infection. These drugs have limited use in actual mastoiditis treatment because they do not easily penetrate the infected bony structure of the mastoid. Cultures of the ear drainage determine which antibiotics should be most effective. Surgical removal of the infected tissue is needed if the infection does not respond to antibiotic therapy within a few days. A simple or modified radical mastoidectomy with tympanoplasty is the most common treatment. All infected tissue must be removed so that the infection does not spread to other structures. A tympanoplasty is then performed to reconstruct the ossicles and the eardrum to restore hearing. Patient preparation, the operative procedure, and follow-up care for tympanoplasty are discussed on pp. 1101 and 1102.

Complications occur when infective material is not removed completely or when other structures are contaminated. Complications include damage to cranial nerves VI and VII, decreasing the patient's ability to look sideways (cranial nerve VI) and causing a drooping of the mouth on the affected side (cranial nerve VII). Other complications include vertigo, meningitis, brain abscess, chronic purulent otitis media, and wound infection.

TRAUMA

Pathophysiology

Trauma and damage may occur to the eardrum and ossicles by infection, by direct damage, or through rapid changes in the middle ear pressure. Foreign objects placed in the external canal exert pressure on the eardrum and cause perforation. If the objects continue through the canal, the bones of the middle ear may be damaged. Blunt injury to the skull and ears can also damage or fracture middle ear structures. Slapping the external ear increases the pressure in the ear canal and can tear the eardrum. The eardrum has a limited stretching ability and gives way under high pressure. Excessive nose blowing and rapid changes of pressure that occur with non-pressurized air flight (**barotrauma**) can increase pressure within the middle ear. High pressure damages the ossicles and can perforate the eardrum.

PATIENT-CENTERED COLLABORATIVE CARE

Most eardrum perforations heal within a week or two without treatment. Repeated perforations, especially from chronic otitis media, heal more slowly, with scarring. Depending on the amount of damage to the ossicles, hearing may or may not return. Hearing aids can improve hearing in this type of hearing loss. Surgical reconstruction of the ossicles and eardrum through a tympanoplasty or a myringoplasty may also improve hearing. (See later discussion of nursing care on p. 1102 in the Tympanoplasty section.)

Nursing care priorities focus on teaching about trauma prevention. Caution patients to avoid inserting objects into the external canal and to follow the steps in [Chart 50-3](#) in [Chapter 50](#) for ear hygiene. Stress the importance of using ear protectors when blunt trauma is likely, especially in sports such as boxing and wrestling.

NEOPLASMS

Tumors of the middle ear are rare, and the most common type is the *glomus jugulare*, a benign lesion arising from the jugular vein. Malignant ear tumors also can occur. The growth of any lesion within the middle ear area disrupts conductive hearing, erodes the ossicles, and may spread to the inner ear and nearby cranial nerves.

Patients have progressive hearing loss and tinnitus. Infection and pain rarely occur with *glomus jugulare* tumors. Otoscopic examination shows a bulging eardrum or a mass extending to the external ear canal. The many blood vessels of the *glomus jugulare* tumor give it a reddish color and a visible pulsation when seen through the eardrum.

Diagnosis is made by physical examination, tomography, and angiography. Tumors are removed by surgery, which often destroys hearing in the affected ear. If all of the edges of the tumor can be seen clearly through the eardrum, surgery is performed through the ear canal to remove the tumor. When the tumor edges extend past the eardrum, more testing is needed to determine the extent of involvement. Radiation therapy is used to decrease the blood supply of the *glomus jugulare* tumor but is not the preferred method of treatment.

TABLE 51-1 RESOURCE AGENCIES FOR EAR AND HEARING IMPAIRMENT

House Research Institute 2100 West Third Street, Fifth Floor Los Angeles, CA 90057 Voice: (800) 388-8612 Fax: (213) 483-8789 www.hei.org E-mail: info@hei.org	American Speech-Language-Hearing Association 2200 Research Boulevard Rockville, MD 20850-3289 Voice: (800) 638-8255 Fax: (301) 296-8580 www.asha.org

Benign tumors are removed because, with continued growth, other structures can be affected, further damaging the facial or trigeminal nerve. When possible, reconstruction of the middle ear structures is performed later to restore conductive hearing.

CONDITIONS AFFECTING THE INNER EAR

TINNITUS

Tinnitus (continuous ringing or noise perception in the ear) is a common hearing problem. Diagnostic testing cannot confirm tinnitus, nor can the disorder be observed. Testing is performed, however, to assess hearing and rule out other disorders.

Manifestation of tinnitus range from mild ringing, which can go unnoticed during the day, to a loud roaring in the ear, which can interfere with thinking and attention span. Some patients feel as if the constant ringing could drive them mad. When patients report tinnitus, consider the many factors that cause tinnitus: presbycusis, **otosclerosis** (irregular bone growth around ossicles), Ménière's disease, certain drugs, exposure to loud noise, and other inner ear problems (Bauer & Brozoski, 2008).

The problem and its management vary with the underlying cause (Newman et al., 2008). When no cause can be found or the disorder is untreatable, therapy focuses on ways to mask the tinnitus with background sound, noise-makers, and music during sleeping hours. Ear mold hearing aids can amplify sounds to drown out the tinnitus during the day. The American Tinnitus Association assists patients in coping with tinnitus. Refer patients with tinnitus to local and online support groups to help cope with this problem (Table 51-1).

VERTIGO AND DIZZINESS

Vertigo and dizziness are common manifestations of many ear disorders. **Dizziness** is a disturbed sense of a person's relationship to space. Patients vary greatly in defining dizziness. Vertigo is often used interchangeably with dizziness, but the definition and cause are somewhat different (Warren, 2008). True **vertigo** is a real sense of whirling or turning in space.

The visual system, the vestibular system (cochlea, semicircular canals), and the proprioceptive system (muscles and nerve endings) combine to give input to the brain about balance. Problems in any of these areas lead to a disturbed sense of balance and motion. Problems that cause vertigo include Ménière's disease, labyrinthitis, acoustic neuromas, motion sickness, and drug or alcohol ingestion.

Manifestations of vertigo include nausea, vomiting, falling, nystagmus, hearing loss, and tinnitus. Until the cause of the vertigo can be identified, each manifestation is treated. Teach patients these strategies to reduce manifestations:

- Restrict head motion and change position slowly.
- Maintain adequate hydration, especially after vomiting.
- Take drugs that reduce the vertigo effects such as over-the-counter dimenhydrinate (Dramamine, Gravol 🍁) or prescription drugs such as diazepam (Valium, Apo-Diazepam 🍁), meclizine (Antivert, Bonamine 🍁), and scopolamine (Transderm Scop, Transderm-V 🍁).

Many patients are dissatisfied with drug side effects, especially drowsiness, which can be worse than the vertigo. Teach patients to maintain a safe, uncluttered environment to prevent accidents during periods of vertigo and to use a cane or walker to maintain balance. Also instruct them to not drive or operate machinery when taking these drugs.

LABYRINTHITIS

Labyrinthitis is an infection of the labyrinth, which may occur as a complication of acute or chronic otitis media. Infection results from an erosion of the bony capsule, allowing organisms to invade the inner ear. Labyrinthitis often results from the growth of a **cholesteatoma** (benign overgrowth of squamous cell epithelium) from the middle ear into the semicircular canal. It may follow middle ear or inner ear surgery when infection is present. Labyrinthitis is often viral in origin and may occur with an upper respiratory infection or mononucleosis.

Manifestations include hearing loss, tinnitus, nystagmus to the affected side, and vertigo with nausea and vomiting. **Meningitis** (infection of the brain covering) is a common complication of labyrinthitis.

Labyrinthitis is usually a self-limiting condition. If it does not resolve with supportive therapy, management includes systemic antibiotics. Teach the patient to complete the antibiotic therapy as prescribed and to not stop taking the drug when manifestations are no longer present. Stopping the drug early can lead to infection recurrence and antibiotic resistance. Advise patients to stay in bed in a darkened room until manifestations are reduced. Antiemetics and antivertiginous drugs, such as dimenhydrinate (Dramamine, Gravol 🍁) and meclizine (Antivert, Bonamine 🍁), relieve symptoms.

The patient also needs psychosocial support. Hearing loss on the affected side may be permanent, although vertigo subsides as the inflammation resolves. Persistent balance problems may improve with gait training and physical therapy.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which problem is most important for the nurse to prevent with a client who has any degree of dizziness from an ear disorder?

- A. Pain
- B. Falls
- C. Dehydration
- D. Hearing loss

MÉNIÈRE'S DISEASE

Pathophysiology

Ménière's disease has three features: tinnitus, one-sided sensorineural hearing loss, and vertigo, occurring in attacks that can last for several days. (Some patients have continuous manifestations of varying intensity rather than intermittent attacks.) Patients are almost totally incapacitated during an attack, and full recovery often takes several days. The pathology of Ménière's disease is an excess of endolymphatic fluid that distorts the entire inner-canal system. This distortion decreases hearing by dilating the cochlear duct, causes vertigo because of damage to the vestibular system, and stimulates tinnitus (Peate, 2009). At first, hearing loss is reversible, but repeated damage to the cochlea from increased fluid pressure leads to permanent hearing loss.

The exact cause of Ménière's disease is unknown, but it often occurs with infections, allergic reactions, and fluid imbalances. Long-term stress may also have a role in the disease.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Ménière's disease usually first occurs in people between the ages of 20 and 50 years. The disease is more common in men and in white people. Severe, debilitating attacks alternate with symptom-free periods. Patients often have certain manifestations before an attack of vertigo, such as headaches, increasing tinnitus, and a feeling of fullness in the affected ear.

Patients describe the tinnitus as a continuous, low-pitched roar or a humming sound, which worsens just before and during an attack. Hearing loss occurs first with the low-frequency tones but worsens to include all levels after repeated episodes. In the early stages of Ménière's disease, hearing is normal or nearly normal between episodes, but permanent hearing loss develops as the attacks increase.

Patients describe the vertigo as periods of whirling, which might even cause them to fall. The vertigo is so intense that even while lying down, the patient often holds the bed or ground to keep from falling. Severe vertigo usually lasts 3 to 4 hours, but he or she may feel dizzy long after the attack. Nausea and vomiting are common. Other manifestations

include rapid eye movements (**nystagmus**) and severe headaches.

INTERVENTIONS

Nonsurgical Management

Teach patients to move the head slowly to prevent worsening of the vertigo. Nutrition and lifestyle changes can reduce the amount of endolymphatic fluid. Encourage patients to stop smoking because of the blood vessel-constricting effects.

Nutrition therapy with a hydrops diet may stabilize body fluid levels to prevent excess endolymph accumulation. The basic structure of this diet involves:

- Distributing food and fluid intake evenly throughout the day and from day to day
- Avoiding foods or fluids that have a high salt content
- Drinking adequate amounts of fluids (low in sugar) daily
- Avoiding caffeine-containing fluids and foods
- Limiting alcohol intake to one glass of beer or wine each day
- Avoiding foods containing monosodium glutamate (MSG)

Coordinate with a dietitian for more detailed information about hydrops diet therapy for reduction of Ménière's manifestations.

Drug therapy may reduce the vertigo and vomiting and restore normal balance. Mild diuretics are prescribed to decrease endolymph volume, which reduces vertigo, hearing loss, tinnitus, and aural fullness. Nicotinic acid has been found to be useful because of its vasodilatory effect. Antihistamines such as diphenhydramine hydrochloride (Benadryl, Allerdryl ☛) and dimenhydrinate (Dramamine, Gravol ☛), and antivertiginous drugs such as meclizine (Antivert, Bonamine ☛), help reduce the severity of or stop an acute attack. Antiemetics such as chlorpromazine hydrochloride (Thorazine, Novo-Chlorpromazine ☛), droperidol (Inapsine), promethazine (Phenergan), and ondansetron (Zofran) help reduce the nausea and vomiting. Diazepam (Valium, Apo-Diazepam ☛) calms the patient; reduces vertigo, nausea, and vomiting; and allows the patient to rest quietly during an attack. Intratympanic therapy with gentamicin and steroids is another method for preventing manifestations; however, some or all hearing is lost in the ear receiving this drug combination.

Another nonsurgical treatment is the Meniett device, which applies low-pressure micropulses to the inner ear for 5 minutes three times daily. This action displaces inner ear fluid and relieves manifestations. Placement of a tympanostomy tube in the eardrum of the affected ear is needed to use this therapy. Long-term success in control of vertigo is over 80%. Although hearing loss is not improved, Meniett device usage does not adversely affect balance, as do most forms of surgical therapy for Ménière's disease.

Surgical Management

For years, surgical treatment of Ménière's disease was a last resort because the hearing in the affected ear was often lost with the more radical procedures. When medical therapy is ineffective and the patient's general function is decreased significantly, surgery may be performed. The choice of the surgical procedure depends on the degree of usable hearing, the severity of the spells, and the condition of the opposite ear.

The most radical procedure involves resection of the vestibular nerve or total removal of the labyrinth (**labyrinthectomy**), performed through the ear canal. The footplate of the stapes is moved aside, and the labyrinth is removed through the oval window.

Another procedure performed early in the course of the disease is endolymphatic decompression with drainage and a shunt (Lee & Pensak, 2008). The effectiveness of this procedure varies. The endolymphatic sac is drained, and a small tube is inserted to improve fluid drainage. Some patients report relief of vertigo with retention of their hearing. If an endolymphatic decompression has been performed, movement of the vestibular structures of the inner ear causes vertigo early after surgery. Reassure the patient that the vertigo is a temporary result of the surgical procedure, not the disease.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

Which new symptom in a 68-year-old man taking diphenhydramine (Benadryl) for vertigo from Ménière's disease will the nurse report to the prescriber?

- A. Decreased urination
- B. Drowsiness
- C. Dry mouth
- D. Cough

ACOUSTIC NEUROMA

An **acoustic neuroma** is a benign tumor of cranial nerve VIII that often damages other structures as it grows. Depending on the size and exact location of the tumor, damage to hearing, facial movements, and sensation can occur (McCance

et al., 2010). An acoustic neuroma can cause many neurologic manifestations as the tumor enlarges in the brain.

Manifestations begin with tinnitus and progress to gradual sensorineural hearing loss in most patients. Later, patients have constant mild to moderate vertigo. As the tumor enlarges, nearby cranial nerves are damaged.

Acoustic neuromas are diagnosed with computed tomography (CT) scanning and magnetic resonance imaging (MRI). Audiograms show sensorineural hearing loss. Cerebrospinal fluid assays show increased pressure and protein.

Surgical removal through a craniotomy is performed, and the remaining hearing is lost. Care is taken to preserve the function of the facial nerve (cranial nerve VII). Care after craniotomy is discussed in Chapter 47. Acoustic neuromas rarely recur after surgical removal.

HEARING LOSS

Pathophysiology

Hearing loss is a common handicap worldwide. It may be conductive, sensorineural, or a combination of the two (Fig. 51-7). Conductive hearing loss occurs when sound waves are blocked from contact with inner ear nerve fibers because of external ear or middle ear disorders. If the inner ear sensory nerve fibers that lead to the cerebral cortex are damaged, the hearing loss is *sensorineural*. Combined hearing loss is *mixed conductive-sensorineural*.

The differences in conductive and sensorineural hearing loss are listed in Table 51-2. Disorders that cause conductive hearing loss are often corrected with minimal or no permanent damage. Sensorineural hearing loss is often permanent, and measures must be taken to prevent further damage or to amplify sounds as a means to improve hearing.

FIG. 51-7 Anatomy of hearing loss. Hearing loss can be divided into three types: (1) conductive (difficulty in the external or the middle ear); (2) sensorineural (difficulty in the inner ear or the acoustic nerve); and (3) mixed conductive-sensorineural (a combination of the two).

TABLE 51-2 DIFFERENTIAL FEATURES OF CONDUCTIVE AND SENSORINEURAL HEARING LOSS

CONDUCTIVE HEARING LOSS	SENSORINEURAL HEARING LOSS
Causes	
Cerumen	Prolonged exposure to noise
Foreign body	Presbycusis
Perforation of the tympanic membrane	Ototoxic substance
Edema	Ménière's disease
Infection of the external ear or middle ear	Acoustic neuroma
Tumor	Diabetes mellitus
Otosclerosis	Labyrinthitis
	Infection
	Myxedema
Assessment Findings	
Evidence of obstruction with otoscope	Normal appearance of external canal and tympanic membrane
Abnormality in tympanic membrane	Tinnitus common
Speaking softly	Occasional dizziness
Hearing best in a noisy environment	Speaking loudly
Rinne test: air conduction greater than bone conduction	Hearing poorly in loud environment
Weber test: lateralization to affected ear	Rinne test: air conduction less than bone conduction
	Weber test: lateralization to unaffected ear

Etiology and Genetic Risk

Conductive hearing loss can be caused by any inflammation or obstruction of the external or middle ear by cerumen or foreign objects. Changes in the eardrum such as bulging, retraction, and perforations may indicate damage to middle ear structures, which leads to conductive hearing loss. Tumors, scar tissue, and overgrowth of soft bony tissue (**otosclerosis**) on the ossicles from previous middle ear surgery also lead to conductive hearing loss.

Sensorineural hearing loss occurs when the inner ear or auditory nerve (cranial nerve VIII) is damaged. Prolonged exposure to loud noise can damage the hair cells of the cochlea. Many drugs are toxic to the inner ear structures, and their effects on hearing can be transient or permanent, dose related or non-dose related, and affect one or both ears. When ototoxic drugs (e.g., those listed in [Table 50-1](#) in

[Chapter 50](#)) are given to patients with reduced kidney function, increased ototoxicity can result because drug elimination is slower. Older patients are especially at risk for ototoxicity because of reduced kidney function.

Presbycusis is a sensorineural hearing loss that occurs as a result of aging ([Ko, 2010](#)). It is caused by breakdown or atrophy of cochlear nerve cells, loss of elasticity of the basilar membrane, or a decreased blood supply to the inner ear. Deficiencies of vitamin B₁₂ and folic acid may play a role in presbycusis. Other causes include atherosclerosis, hypertension, infections, fever, Ménière's disease, diabetes, and ear surgery. Each disorder accelerates degenerative changes of the cochlea ([Touhy & Jett, 2010](#)). Trauma to the ear also contributes to sensorineural hearing loss ([Laubach, 2010](#)).

Incidence/Prevalence

Because hearing loss may be gradual and affect only some aspects of hearing, many adults are unaware that their hearing is impaired. The actual incidence of hearing loss is not known, but hearing loss dramatically increases among people in their 70s and 80s ([Pratt et al., 2009](#)) (see the Evidence-Based Practice box on p. 1099).

Health Promotion and Maintenance

For most people, hearing is an important factor in social interactions and to gain knowledge. With special care to the ears, hearing can be preserved at maximum levels. Address barriers to the use of hearing protection, exposure to loud music, and other modifiable risk factors that lead to hearing loss ([Stephenson, 2009](#)). Encourage everyone to have simple hearing testing performed as part of their annual health assessment.

Teach everyone the danger in using foreign objects (e.g., bobby-pins, Q-tips, toothpicks, keys) to clean the ear canal. These objects can scrape the skin of the canal, push cerumen up against the eardrum, and even puncture the eardrum. Explain that nothing smaller than a person's own fingertip should be inserted into the canal. If cerumen buildup is a problem, teach the person to use an ear irrigation syringe and proper solutions to remove it. ([Chart 50-3](#) in [Chapter 50](#) describes techniques to remove cerumen safely.)

Teach all people about protecting their ears from loud noises by wearing protective ear devices, such as over-the-ear headsets or foam ear inserts, when exposed to persistent loud noises. Suggest the use of earplugs when engaging in water sports to prevent ear infections, as well as using an over-the-counter product such as Swim-Ear to assist with drying the ear after swimming.

GENETIC/GENOMIC CONSIDERATIONS

Some types of hearing loss in adults can have a genetic origin. Some syndromes in which a single gene mutation results in many abnormal manifestations also increase the risk for progressive hearing loss in adults. Two such syndromes are Usher's syndrome and Alport's syndrome ([Nussbaum et al., 2007](#)). Usher's syndrome, in addition to hearing loss, occurs with blindness as a result of retinitis pigmentosa. This syndrome has an autosomal recessive pattern of inheritance. Alport's syndrome, which causes abnormal kidney function in addition to hearing loss, has many forms and many patterns of inheritance. One type of adult-onset hearing loss that does not have any other physical problems is associated with a mutation in the *GJB2* gene on chromosome 1 ([Online Mendelian Inheritance in Man \[OMIM\], 2010](#)). This problem has an autosomal dominant pattern of inheritance.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

Ask patients how long they have noticed a difference in their hearing and whether the changes occurred suddenly or gradually. Age is an important factor, because some ear and hearing changes occur with advancing age. Chronic otitis media occurs more often in the older adult. Ask about occupational exposure to loud or continuous noises, as well as current or previous use of ototoxic drugs. Also ask about any

EVIDENCE-BASED PRACTICE

What Is the Incidence of Hearing Loss Among Older Adults?

Pratt, S.R., Kuller, L., Talbott, E.O., McHugh-Pemu, K., Buhari, A.M., & Xu, X. (2009). Prevalence of hearing loss in black and white elders: Results of the cardiovascular health study. *Journal of Speech, Language, and Hearing Research*, 52(4), 973-989.

Hearing loss is more common among older adults; however, the actual incidence and the personal characteristics more closely associated with hearing loss are not known. The purpose of this study was to determine the influence of age, gender, and race on both the incidence and severity of hearing loss. The subjects were 548 persons who were part of a cohort of participants in a large cardiovascular health cohort study sponsored by the National Heart, Lung, and Blood Institute of the National Institutes of Health; they represented a cross-section of the original 5201 members of the original cohort. Subjects ranged in age from 72 to 96 years and consisted of 48 black men, 74 black women, 179 white men, and 247 white women. Hearing was assessed after otoscopic examination determined no impediment to conduction through the ear canal existed. Hearing tests were performed by audiologists using pure-tone air-conduction testing measuring standard and extended high-frequency thresholds. In addition to descriptive statistics, multiple linear regression analyses were performed to examine relationships between hearing and variables of age, gender, race, smoking, and cardiovascular disease.

Age was the most significant contributor to hearing loss, with subjects in their 80s experiencing greater and more severe hearing loss than those in their 70s. Overall, men had more hearing loss than women and hearing loss was greater among whites than among blacks. A surprising outcome of the study was that neither smoking history nor cardiovascular disease had a negative effect on hearing.

Level of Evidence: 4

Although very large, the study was descriptive in nature without randomization of subject selection or assignment. The methods of statistical analysis were appropriate for the research questions posed.

Commentary: Implications for Practice and Research

The results of this study indicated that more than 50% of adults older than 80 years experienced significant hearing loss, especially men. Nurses must consider this when communicating with older adults, especially during assessment and teaching sessions when miscommunication could result in serious problems. Although nurses should not assume that all older adults have a hearing loss, it is important to use communication techniques that improve information transfer in all situations. These include:

- Facing the patient during any communication
- Ensuring that your mouth is visible to the patient when you speak
- Making the environment as quiet as possible (turning radios and televisions off or down, closing the door to the hall, moving to a treatment room or conference room if the noise in the room is too loud and cannot be managed)
- Speaking clearly and at a pace that is slightly slower (such as that you would use for public speaking)
- Asking the patient to repeat the main points of what has been said in his or her own words
- Observing the patient's face and body language for cues that communication is effective or ineffective

history of external ear or middle ear infection and whether eardrum perforation occurred. Ask patients about any direct trauma to the ears. Because some types of hearing loss have a genetic basis, ask whether any family members are hearing impaired. When pain occurs with acute-onset hearing loss,

CHART 51-5 FOCUSED ASSESSMENT

The Patient with Suspected Hearing Loss

Assess whether the patient has any of these ear problems:

- Pain
- Feeling of fullness or congestion
- Dizziness or vertigo
- Tinnitus
- Difficulty understanding conversations, especially in a noisy room
- Difficulty hearing sounds
- The need to strain to hear
- The need to turn the head to favor one ear or the need to lean forward to hear

Assess visible ear structures, particularly the external canal and tympanic membrane:

- Position and size of the pinna
- Patency of the external canal; presence of cerumen or foreign bodies, edema, or inflammation
- Condition of the tympanic membrane: intact, edema, fluid, inflammation

Assess functional ability, including:

- Frequency of asking people to repeat statements
- Withdrawal from social interactions or large groups
- Shouting in conversation
- Failing to respond when not looking in the direction of the sound
- Answering questions incorrectly

ask about recent upper respiratory infection and allergies affecting the nose and sinuses.

Physical Assessment/Clinical Manifestations

Chart 51-5 lists focused assessment techniques for patients with suspected hearing loss. Hearing loss may be sudden or gradual and often affects both ears. The ability to hear high-frequency soft consonants—especially *s*, *sh*, *f*, *th*, and *ch* sounds—is lost first. Patients often state that they have no problem with hearing but cannot understand specific words. They might think that the speaker is mumbling. They often have continuous tinnitus in both ears. Vertigo may be present, depending on the extent of inner ear involvement.

Tuning fork tests help diagnose hearing loss (see Chapter 50). With the Weber test, the patient can usually hear sounds well in the ear with a conductive hearing loss because of bone conduction. With the Rinne test, the patient reports that sound transmitted by bone conduction is louder and more sustained than that transmitted by air conduction.

Otoscopic examination is performed to assess the external ear canal, the eardrum, and structures of the middle ear that can be seen through the eardrum (see Chapter 50). Findings from examination vary, depending on the cause of the hearing loss.

External ear canal obstruction can result in hearing loss. Inspect the canal, looking for:

- Whether the canal is open
- The amount and character of cerumen present
- The integrity of the skin lining the canal
- The presence of redness, exudates, lesions, or foreign objects

Middle ear infections can also reduce hearing. In infection or inflammation, the eardrum appears red, thickened, and bulging, with a loss of landmarks. Loss of eardrum mobility

is seen with inspection through a pneumatic otoscope. Document the presence of scars or perforations on the eardrum.

Psychosocial Assessment

For people with a hearing loss, communication can become a struggle and they may isolate themselves because of the difficulty in talking and listening. Social isolation can lead to depression, fear, and despair. Be sensitive to emotional changes that may be related to reduced hearing and a decline in conversational skills. Encourage the patient and family to express their feelings and concerns about an actual or potential hearing loss.

Laboratory Assessment

No laboratory test diagnoses hearing loss. However, some laboratory findings can indicate problems that affect hearing.

White blood cell counts are elevated in the patient with acute or chronic otitis media. Microbial culture and antibiotic sensitivity tests can determine the causative organism and appropriate drug therapy when infection causes hearing loss.

The patient with hearing loss from peripheral neuropathy may have other systemic diseases, including human immune deficiency virus (HIV) disease or diabetes. Patients undergoing cancer chemotherapy or interferon therapy are at risk for neuropathic hearing loss.

Imaging Assessment

Imaging assessment can determine non-auditory problems affecting hearing ability. Skull x-rays are used to determine bony involvement in otitis media and the location of otosclerotic lesions, and CT and MRI are used to determine soft-tissue involvement and the presence and location of tumors.

Other Diagnostic Assessment

Audiometry can help determine the extent and type of hearing loss. An audiogram shows whether hearing loss is only conductive or whether it has a sensorineural component. This is important in determining possible causes of the hearing loss and in planning interventions.

ANALYSIS

The priority problems for the patient with any degree of hearing impairment are:

1. Difficulty hearing related to obstruction, infection, damage to the middle ear, or damage to the auditory nerve
2. Potential for reduced communication related to difficulty hearing

PLANNING AND IMPLEMENTATION

Increasing Hearing

Planning: Expected Outcomes. The patient with hearing impairment is expected to either have an increase in functional hearing or maintain existing hearing levels. Indicators include:

- No or minimal loss of high pitch tones
- No or minimal loss of ability to distinguish conversation from background environmental noise
- Turning toward sound
- Identifying discrete sounds

Interventions. Interventions are expected to identify the problem, halt the pathologic processes, and increase usable hearing. Nursing care priorities focus on teaching the patient about the use and care of an appropriate assistive device, providing support to the patient and family who are working to maintain or increase communication, and assisting patients to find local and Internet-based support services.

Nonsurgical Management. Interventions include early detection of hearing impairment, use of drug therapy and comfort measures, and use of assistive devices to amplify or augment the patient's usable hearing.

Early detection helps correct the problem causing the hearing loss. Assess for indications of hearing loss, as listed in [Chart 51-5](#).

Drug therapy is focused on either correcting the underlying pathologic change or reducing the side effects of problems occurring with hearing loss. Topical antibiotics are given to patients with external otitis. Systemic antibiotics are needed when patients have other ear infections. Teach the patient receiving antibiotic therapy the importance of taking the drug or drugs exactly as prescribed and completing the entire course. Caution him or her to not stop the drug just because manifestations have improved. By treating the infection, antibiotics reduce local edema and improve hearing. When pain occurs with hearing disorders, analgesics are used, depending on the location and type of pain. Many ear disorders disturb equilibrium, causing vertigo and dizziness with nausea and vomiting. Antiemetic, antihistamine, antivertiginous, and benzodiazepine drugs can help correct nausea, vertigo, and dizziness.

Assistive devices are useful for patients with permanent, progressive hearing loss. Portable amplifiers can be used while watching television to avoid increasing the volume and disturbing others. Telephone amplifiers increase telephone volume, allowing the caller to speak in a normal voice. Flashing lights activated by the ringing telephone or a doorbell alert patients visually. In some cases, patients may have a specially trained dog to help them be aware of sounds (ringing telephones or doorbells, cries of other people, and potential dangers), in much the same way that a seeing-eye dog assists a blind person. Provide information about agencies that can assist the hearing-impaired person.

Small, portable audio amplifiers can assist in communicating with patients with hearing loss but who have chosen not to use a hearing aid. The use of audio amplifiers or allowing patients to use a stethoscope for listening helps you communicate with anyone who requires additional volume to hear speech.

A hearing aid is a miniature electronic amplifier that is usually used for patients with conductive hearing loss. Hearing aids are less effective for sensorineural hearing loss and may make hearing worse by amplifying background noise. The amplifier can be worn in one or both ears. Some hearing-impaired patients refuse to use hearing aids, believing that other people will think they are old. Most common hearing aids are small. Some are attached to a person's glasses and are visible to other people. Another type fits into the ear and is less noticeable. Newer devices fit completely in the canal with only a fine, clear filament visible. The cost of smaller hearing aids is greater than the cost of larger ones. Local agencies offer special classes for the hearing impaired that help the users benefit from this device.

Offer some special tips to help the patient adjust to the hearing aid. Hearing with a hearing aid is different from natural hearing. Teach the patient to start using the hearing aid slowly, at first wearing it only at home and only during part of the day. Listening to television and the radio and reading aloud can help the patient get used to new sounds. The tone or volume of the hearing aid can be adjusted. A difficult aspect of a hearing aid is the amplification of background noise. The patient must learn to concentrate and filter out background noises.

Teach the patient how to care for the hearing aid (Chart 51-6). Hearing aids are delicate devices that should be handled

CHART 51-6 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Hearing Aid Care

- Keep the hearing aid dry.
- Clean the ear mold with mild soap and water while avoiding excessive wetting.
- Clean debris from the hole in the middle of the part that goes into your ear with a toothpick.
- Turn off the hearing aid and remove the battery when not in use.
- Check and replace the battery frequently.
- Keep extra batteries on hand.
- Keep the hearing aid in a safe place.
- Avoid dropping the hearing aid or exposing it to temperature extremes.
- Adjust the volume to the lowest setting that allows you to hear, to prevent feedback squeaking.
- Avoid using hair spray, cosmetics, oils, or other hair and face products that might come into contact with the receiver.
- If the hearing aid does not work:
 - Change the battery.
 - Check the connection between the ear mold and the receiver.
 - Check the on/off switch.
 - Clean the sound hole.
 - Adjust the volume.
 - Take the hearing aid to an authorized service center for repair.

only by people who know how to care for them properly. The cost of the aids varies greatly but is a significant investment.

Cochlear implantation may help patients with sensorineural hearing loss. Although a superficial surgical procedure is needed to implant the device, the procedure does not enter the inner ear and thus is not considered a surgical correction for hearing impairment. A small computer converts sound waves into electronic impulses. Electrodes are placed near the internal ear, with the computer attached to the external ear. The electronic impulses then directly stimulate nerve fibers. Some patients have a 50% return of their hearing with this method (Bassim & Fayad, 2010).

Surgical Management. Many surgical interventions are available for patients with specific disorders leading to hearing loss.

Tympanoplasty. Tympanoplasty reconstructs the middle ear to improve conductive hearing loss. The procedures vary from simple reconstruction of the eardrum (**myringoplasty**) to replacement of the ossicles within the middle ear (**ossiculoplasty**). A type I tympanoplasty is used for a myringoplasty; a type II tympanoplasty is used in cases of greater damage, and it provides more extensive reconstruction (Fig. 51-8).

Preoperative Care. The patient requires specific instructions before surgery. Systemic antibiotics reduce the risk for infection. Before surgery, irrigate the ear with a solution of equal parts of vinegar and sterile water to restore normal ear pH. Teach the patient to follow other measures to decrease the risks for infection, such as avoiding people with upper respiratory infections, getting adequate rest, eating a balanced diet, and drinking adequate amounts of fluid.

Assure the patient that hearing loss immediately after surgery is normal because of canal packing and that hearing will improve when it is removed. Teach about deep breathing and coughing after surgery, but stress that forceful coughing increases middle ear pressure and must be avoided.

Operative Procedures. Surgery is performed only when the middle ear is free of infection. If an infection is present, the graft is more likely to become infected and not heal. Surgery

FIG. 51-8 A normal tympanic membrane and two types of tympanoplasties.

FIG. 51-9 Surgical approaches for the ear. The endaural approach is used when the external canal is too small to use for a transcanal approach. The postauricular approach is used for more extensive repair of the middle ear and inner ear structures.

of the eardrum and ossicles requires the use of a microscope and is a delicate procedure. Local anesthesia can be used, although general anesthesia is often used to prevent the patient from moving.

The surgeon can repair the eardrum with many materials, including muscle fascia, a skin graft, and venous tissue. If the ossicles are damaged, more extensive surgery is needed for repair or replacement. The ossicles can be reached in several ways—through the ear canal, with an endaural incision, or by an incision behind the ear with a mastoidectomy (Fig. 51-9).

The surgeon removes diseased tissue and cleans the middle ear cavity. The ossicles are assessed for damage and the extent of needed repair or replacement. The patient's cartilage or bone, cadaver ossicles, stainless steel wire, or special polymers (Teflon) are used to repair or replace the ossicles.

Postoperative Care. An antiseptic-soaked gauze, such as iodoform gauze (NU GAUZE), is packed in the ear canal. If a skin incision is used, a dressing is placed over it. Keep the dressing clean and dry, using sterile technique for changes. Keep the patient flat, with the head turned to the side and the operative ear facing up for at least 12 hours after surgery. Give prescribed antibiotics to prevent infection.

Patients often report hearing improvement after removal of the canal packing. Until that time, communicate as with a hearing-impaired patient, directing conversation to the unaffected ear. Instruct the patient in care and activity restrictions (see Chart 51-4).

CHART 51-7 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF MANAGEMENT

Prevention of Ear Infection or Trauma

- Do not use small objects, such as cotton-tipped applicators, matches, toothpicks, keys, or hairpins, to clean your external ear canal.
- Wash your external ear and canal daily in the shower or while washing your hair.
- Blow your nose gently.
- Do not occlude one nostril while blowing your nose.
- Sneeze with your mouth open.
- Wear sound protection around loud or continuous noises.
- Avoid activities with high risk for head or ear trauma, such as wrestling, boxing, motorcycle riding, and skateboarding; wear head and ear protection when engaging in these activities.
- Keep the volume on head receivers at the lowest setting that allows you to hear.
- Frequently clean objects that come into contact with your ear (e.g., headphones, telephone receivers).
- Avoid environmental conditions with rapid changes in air pressure.

Stapedectomy. A partial or complete stapedectomy with a prosthesis corrects some types of hearing loss. This procedure is most effective for patients with hearing loss related to otosclerosis. The average age for patients undergoing primary stapes surgery is increasing. Regardless of age, hearing usually improves after primary stapes surgery; however, some patients redevelop conductive hearing loss after surgery and revision surgery is needed.

Preoperative Care. To prevent infection, the patient must be free from external otitis at surgery. Teach the patient to follow measures that prevent middle ear or external ear infections (Chart 51-7).

Review with the patient the expected outcomes and possible complications of the surgery. Hearing is initially worse after a stapedectomy. The success rate of this procedure is high. However, there is always a risk for failure that might lead to total deafness on the affected side. Possible complications include vertigo, infection, and facial nerve damage, and the patient must understand these risks before proceeding with surgery.

Operative Procedures. A stapedectomy is usually performed through the external ear canal with the patient under local anesthesia. The head and neck of the stapes and, less often, the footplate are removed. After removal of the bone, a small hole is drilled or made with a laser in the footplate and a prosthesis in the shape of a piston is connected between the incus and the footplate (Fig. 51-10). Sounds cause the prosthesis to vibrate as the stapes did. After stapedectomy, most patients have restoration of functional hearing.

Postoperative Care. Inform the patient that improvement in hearing may not occur until 6 weeks after surgery. At first, the ear packing interferes with hearing. Swelling after surgery reduces hearing but is temporary. Drugs for pain help reduce discomfort, and antibiotics are used to reduce the risk for infection. Teach the patient to follow the procedures in Chart 51-4.

The surgical procedure is performed in an area where cranial nerves VII, VIII, and X can be damaged by trauma or by swelling after surgery. *Assess for facial nerve damage or*

FIG. 51-10 Prosthesis used with stapedectomy. The stapes is removed, leaving the footplate. After a hole is made in the footplate, a metal or plastic prosthesis is connected to the incus and inserted through the hole to act as a vibration device, much as the stapes worked before the development of otosclerosis.

muscle weakness. Indications include an asymmetric appearance or drooping of features on the affected side of the face. Ask the patient about changes in facial perception of touch and in taste. Vertigo, nausea, and vomiting are common after surgery because of the nearness to inner ear structures.

Antivertiginous drugs, such as meclizine (Antivert, Bonamine ) and antiemetic drugs, such as droperidol (Inapsine), are given. Take care to prevent injury, especially during times of increased vertigo.

! NURSING SAFETY PRIORITY

Action Alert

Prevent injury by assisting the patient with ambulation during the first 1 to 2 days after stapedectomy. In addition, keep top bed siderails up, and remind the patient to move his or her head slowly when changing position to avoid vertigo.

Totally Implanted Devices. A newly approved device to treat bilateral moderate to severe sensorineural hearing loss is the Esteem system. It is designed to improve hearing to the same or better level as a high quality hearing aid but without any visible part. The device has three components that are totally implanted: a sound processor, a sensor, and a computer driver. Vibrations of the eardrum and ossicles are picked up by the sensor and converted to electric signals that are processed by the sound processor. Each processor is specifically programmed to the patient's specific hearing pathology. The processor filters out some background noise and amplifies the desired sound signal, which is then transferred to the driver. The driver then converts the processed signal into vibrations that are transmitted to the inner ear for sound perception (U.S. Food and Drug Administration, 2010).

Patient criteria for this new device include:

- Bilateral stable sensorineural hearing loss determined by pure-tone audiometry
- Speech discrimination score of 40% or higher (see Chapter 50)
- Healthy tympanic membrane, eustachian tube, and ossicles of the middle ear

CHART 51-8 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Communicating with a Hearing-Impaired Patient

- Position yourself directly in front of the patient.
- Make sure that the room is well lighted.
- Get the patient's attention before you begin to speak.
- Move closer to the better-hearing ear.
- Speak clearly and slowly.
- Do not shout (shouting raises the frequency of the sound and often makes understanding more difficult).
- Keep hands and other objects away from your mouth when talking to the patient.
- Attempt to have conversations in a quiet room with minimal distractions.
- Have the patient repeat your statements rather than just indicate assent.
- Rephrase sentences and repeat information to aid in understanding.
- Use appropriate hand motions.
- Write messages on paper if the patient is able to read.

- Large enough space in the ear cavity to accommodate the parts of the device
- Minimum of 30 days of experience with an appropriately fitted hearing aid
- Absence of acute or chronic middle ear, inner ear, or mastoid infection
- Absence of Ménière's disease or recurring vertigo that requires treatment
- Absence of excessive sensitivity to silicone rubber, polyurethane, stainless steel, titanium, or gold

Possible complications of the device and the surgery required to implant it include:

- Temporary facial paralysis
- Changes in taste sensation
- Ongoing or new-onset tinnitus

Unlike more standard cochlear implants, the middle ear is entered and it is considered a surgical procedure. Care before and after surgery is similar to that required with stapedectomy. A distinct disadvantage is the cost of the implant and procedure, which exceeds \$30,000 and is not currently covered by insurance.

Maximizing Communication

Planning: Expected Outcomes. The patient with hearing loss or impairment is expected to become proficient in hearing compensation behaviors to maintain or improve communication. Indicators include that the patient consistently demonstrates these behaviors:

- Uses hearing assistive devices
- Cares for external hearing assistive devices
- Uses sign language, lip-reading, or closed captioning (for television viewing)
- Accurately interprets messages
- Uses nonverbal language
- Exchanges messages accurately with others

Interventions. Nursing priorities focus on facilitating communication and reducing anxiety.

Use best practices that are listed in Chart 51-8 for communicating with a hearing-impaired patient. Do not shout at the patient because the sound may be projected at a higher

frequency, making him or her less able to understand. The most obvious means of communicating is by the written word (if he or she is able to see, read, and write) or with pictures of familiar phrases and objects. Many television programs are now closed captioned (subtitled).

Assistive devices, described on p. 1100, can greatly increase communication for the patient with a hearing impairment.

Lip-reading and *sign language* can also increase communication. In lip-reading classes, patients are taught the special cues to look for when lip-reading and how to understand body language. However, the best lip-reader still misses more than half of what is being said. Because hearing is assisted by even minimal lip-reading, urge patients to wear their eyeglasses when talking with someone to see lip movement.

Sign languages, such as American Sign Language (ASL), combine speech with hand movements that signify letters, words, and phrases. These languages take time and effort to learn, and many people cannot learn them, just as many people cannot learn foreign languages.

Managing anxiety can increase the effectiveness of communication efforts. One source of anxiety is the possibility of permanent hearing loss. Provide accurate information about the likelihood of hearing returning. When the hearing impairment is likely to be permanent or become more profound, reassure patients that communication and social interaction can be maintained.

To reduce anxiety and prevent social isolation, assist patients to use resources and communication to make social contact satisfying. Ask about past or present diversional activities to identify the patient's most satisfying activities and social interactions, and determine the effort necessary to continue them. Activities can be altered to improve patient satisfaction. Someone accustomed to large gatherings might choose smaller groups instead. A quiet evening meal at home with friends might substitute for dinner in a noisy restaurant.

Community-Based Care

Lengthy hospitalization is rare for most patients with ear and hearing disorders. If surgical repair is needed and the procedure is completed without complications, the procedure may be completed in an ambulatory setting or the hospital stay is usually only 1 day.

Home Care Management

Patients who have persistent vertigo, either with the disorder or as a side effect of surgery, remain in danger of falling. Assess the home for potential hazards and to determine whether family members or significant others are available to assist with meal preparation and other ADLs. A nurse case manager can coordinate with the home care nurse to assist patients and their families in determining the best ways to maintain adequate self-care abilities, maintain a safe environment, decide about assistance needs, and provide needed care.

Teaching for Self-Management

Give patients written instructions about how to take drugs and when to return for follow-up care. If the patient cannot read, give these instructions to a family member who may assist with care. Teach patients how to instill eardrops (see [Chart 51-1](#)) and irrigate the ears (see [Chart 51-2](#)), and obtain a return demonstration.

To prevent infection after surgery, instruct patients to follow the suggestions in [Chart 51-7](#). For patients who use a hearing aid, teach them how to use it effectively.

Health Care Resources

If patients do not have family or friends to help during the time before or after surgery, a referral to a home care agency is needed. Help with meal preparation, cleaning, and personal hygiene can be arranged by the hospital discharge planners.

Follow-up hearing tests are scheduled when the lesions are well healed, in about 6 to 8 weeks. Audiograms done before and after treatment are compared, and evaluation for further intervention to improve hearing begins. A complication of surgery is continued disability or complete loss of hearing in the affected ear. Surgery is performed on the ear with the greatest hearing loss. If the surgery does not improve hearing, patients must decide to either attempt surgical correction of the other ear or continue to use an amplification device. When the underlying disorder causing the hearing impairment is progressive, this decision is difficult. Support patients by listening to their concerns and giving additional information when needed.

Costs to the person with a hearing impairment can be extensive. Information and support can come from several organizations that publish informative articles to help patients reduce hearing loss (see [Table 51-1](#)). Many public and private agencies offer hearing evaluations, as well as supply information and counseling for patients with hearing disorders.

EVALUATION: OUTCOMES

Evaluate the care of the patient with hearing loss or hearing impairment based on the identified priority patient problems. The expected outcomes include that the patient will:

- Have at least partial improvement of hearing
- Have minimal anxiety
- Use appropriate hearing compensation behaviors
- Be able to communicate effectively with family, friends, co-workers, and health care professionals

Specific indicators for these outcomes are listed for each priority problem under the Planning and Implementation section (see earlier).

DECISION-MAKING CHALLENGE

Patient-Centered Care

The patient is a 48-year-old man who is an advertising executive in a large agency. He has recently been diagnosed with bilateral sensorineural hearing loss. His other health issues include hypertension (which he manages with losartan [Cozaar]) and gastroesophageal reflux disease (which he manages with esomeprazole [Nexium]). He also has completed chemotherapy for Hodgkin's lymphoma within the past 6 months. He is surprised by his diagnosis because he works at keeping himself physically fit. He is distraught and very concerned that his co-workers will consider him "over the hill" with an "old man's" disease. He says that using a hearing aid is out of the question.

1. Is there any possibility that his hearing loss is related to current or past health problems? If so, which one(s) and why?
2. What additional personal and family information should you obtain from this patient?
3. How would you approach his concern about being considered old?
4. What options are available to improve his hearing?

NURSING CONCEPT REVIEW

What might you NOTICE if the patient is experiencing hearing problems?

- Person tilts one side of the head or leans forward to listen when another person speaks.
- Person watches the lips of a speaker closely.
- Person does not startle when a loud or unexpected sound occurs in the environment.
- Person frequently asks the speaker to repeat statements or questions.
- Person does not verbally interact with those around him or her.
- When a sentence is whispered to the person, he or she does not accurately repeat it back to the speaker.
- Person responds inappropriately to questions. For example, if asked “Is the room too cold?” the patient may respond “No, I don’t feel old.”

How should you RESPOND to a patient experiencing hearing problems?

- Reduce the background sound when speaking to the person (close the door to the hall, use a private area, turn off televisions and radios).
- Speak slowly, distinctly, and with a deeper tone.
- Face the patient while speaking.
- Ensure that all members of the health care team are aware of the patient’s impairment and use an appropriate method to communicate with the patient.
- Determine whether the patient can communicate by sign language.
- Identify safety issues specific for the patient with a hearing impairment.
- Use a certified medical interpreter when taking a history from, explaining procedures to, or teaching the patient who has a hearing impairment.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Use Contact Precautions with any patient who has drainage from the ear canal.
- Avoid performing an otoscopic examination on a confused or uncooperative patient.
- Use the suggestions presented under History in the Hearing Loss section to enhance communication with a patient who has a hearing impairment.
- Protect the patient with vertigo or dizziness from injury, and assist with ambulation.

Health Promotion and Maintenance

- Teach patients the proper way to clean the pinna and external ear canal.
- Encourage all patients, even if they already have a hearing impairment, to use ear protection in a loud environment.
- Teach patients how to properly care for their hearing aids.
- Instruct patients to avoid closing off one naris when blowing the nose.
- Remind patients who engage in water sports and who are at risk for external otitis to wear earplugs when in the water.
- Teach proper ear hygiene for cleaning cerumen from the external canal.

- Urge everyone to avoid exposure to loud noises for extended periods without proper OSHA-approved ear protection.

Psychosocial Integrity

- Encourage the patient and family to express feelings and concerns about a change in hearing status.
- Refer patients newly diagnosed with hearing impairment or any chronic ear problem to appropriate local resources and support groups.
- Explain therapeutic procedures, restrictions, and follow-up care to the patient and family.
- Teach family members ways to communicate with a hearing-impaired patient with and without a hearing aid.

Physiological Integrity

- Ask the patient about hearing problems in any other members of the family, because many hearing problems have a genetic component.
- Check the hearing of any patient receiving an ototoxic drug (Table 50-1 in Chapter 50) for more than 5 days.
- Teach patients the proper techniques for self-instillation of eardrops and ear irrigation.
- Stress the importance of completing an antibiotic regimen for an ear infection.
- Follow the guidelines in Chart 51-2 when irrigating the ear canal.
- Avoid ear canal irrigation if the eardrum is perforated or if the canal contains vegetative matter.

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Collaborate with the physical and occupational therapists to perform a complete musculoskeletal assessment, including functional status, as needed.

Health Promotion and Maintenance

2. Explain how physiologic aging changes of the musculoskeletal system affect care of older adults.

Psychosocial Integrity

3. Assess the patient's and family's reaction to change in body image caused by a major musculoskeletal health problem.
4. Recognize the importance of support systems and effective strategies for the patient with unexpected altered body image caused by a musculoskeletal health problem.

Physiological Integrity

5. Recall the anatomy and physiology of the musculoskeletal system.
6. Conduct a musculoskeletal history using Gordon's Functional Health Patterns.
7. Assess patients for mobility, gait, motor skills, pain, and the use of assistive devices.
8. Interpret assessment findings in a patient with a musculoskeletal health problem.
9. Assess patients regarding iodine allergy before imaging assessments.
10. Explain the use of laboratory testing for a patient with a musculoskeletal health problem.
11. Develop a teaching plan to educate the patient and family about diagnostic procedures.

The musculoskeletal system is the second largest body system. It includes the bones, joints, and skeletal muscles, as well as the supporting structures needed to move them. *Mobility* (movement) is a basic human need that is essential for performing ADLs. When a patient cannot move to perform ADLs or other daily routines, self-esteem and a sense of self-worth can be diminished.

Disease, surgery, and trauma can affect one or more parts of the musculoskeletal system, often leading to decreased mobility. When mobility is impaired for a long time, other body systems can be affected. For example, prolonged immobility can lead to skin breakdown, constipation, and thrombus formation. If nerves are damaged by trauma or disease, patients may also have problems with *sensation*.

ANATOMY AND PHYSIOLOGY REVIEW

Skeletal System

The skeletal system consists of 206 bones and multiple joints. The growth and development of these structures occur during childhood and adolescence and are not discussed in this text. Common physical skeletal differences among ethnic groups are listed in Table 52-1.

Bones

Types and Structure. Bone can be classified in two ways—by shape and by structure. **Long bones**, such as the femur, are cylindric with rounded ends and often bear weight. **Short bones**, such as the phalanges, are small and bear little or no weight. **Flat bones**, such as the scapula, protect vital organs and often contain blood-forming cells. Bones that have unique shapes are known as **irregular bones**. The carpal bones in the wrist and the small bones in the inner ear are examples of irregular bones. The **sesamoid bone** is the least common type and develops within a tendon; the patella is a typical example.

The second way bone is classified is by *structure* or composition. As shown in Fig. 52-1, the outer layer of bone, or

cortex, is composed of dense, compact bone tissue. The inner layer, in the medulla, contains spongy, cancellous tissue. Almost every bone has both tissue types but in varying quantities. The long bone typically has a shaft, or **diaphysis**, and two knoblike ends, or **epiphyses**.

The structural unit of the cortical compact bone is the haversian system, which is detailed in Fig. 52-1. The haversian system is a complex canal network containing microscopic blood vessels that supply nutrients and oxygen to bone, as well as lacunae, which are small cavities that house **osteocytes** (bone cells). The canals run vertically within the hard cortical bone tissue.

The softer **cancellous** tissue contains large spaces, or trabeculae, which are filled with red and yellow marrow. **Hematopoiesis** (production of blood cells) occurs in the red marrow. The yellow marrow contains fat cells, which can be dislodged and enter the bloodstream to cause fat embolism syndrome (FES), a life-threatening complication. Volkmann's canals connect bone marrow vessels with the haversian system and periosteum, the outermost covering of the bone. In the deepest layer of the periosteum are osteogenic cells, which later differentiate into **osteoblasts** (bone-forming cells) and **osteoclasts** (bone-destroying cells).

Bone also contains a **matrix**, or **osteoid**, consisting chiefly of collagen, mucopolysaccharides, and lipids. Deposits of inorganic calcium salts (carbonate and phosphate) in the matrix provide the hardness of bone.

FIG. 52-1 The structure of a typical long bone. The cortex, or outer layer, is composed of dense, compact tissue. The microscopic structure of this compact cortical tissue is the haversian system.

TABLE 52-1 MUSCULOSKELETAL DIFFERENCES IN SELECTED GROUPS

GROUP	MUSCULOSKELETAL DIFFERENCES
African Americans	Greater bone density than Europeans, Asians, and Hispanics. Accounts for decreased incidence of osteoporosis.
Amish	Greater incidence of dwarfism than in other populations.
Chinese Americans	Bones are shorter and smaller with less bone density. Increased incidence of osteoporosis.
Egyptian Americans	Shorter in stature than Euro-Americans and African Americans.
Filipino/Vietnamese	Short in stature; adult height about 5 feet.
Irish Americans	Taller and broader than other Euro-Americans. Less bone density than African Americans.
Navajo American Indians	Taller and thinner than other American Indians.

Bone is a very vascular tissue. Its estimated total blood flow is between 200 and 400 mL/min. Each bone has a main nutrient artery, which enters near the middle of the shaft and branches into ascending and descending vessels. These vessels supply the cortex, the marrow, and the haversian system. Very few nerve fibers are connected to bone. Sympathetic nerve fibers control dilation of blood vessels. Sensory nerve fibers transmit pain signals experienced by patients who have primary lesions of the bone, like bone tumors.

Function. The skeletal system:

- Provides a framework for the body and allows the body to be weight bearing, or upright
- Supports the surrounding tissues (e.g., muscle and tendons)
- Assists in movement through muscle attachment and joint formation
- Protects vital organs, such as the heart and lungs
- Manufactures blood cells in red bone marrow
- Provides storage for mineral salts (e.g., calcium and phosphorus)

After puberty, bone reaches its maturity and maximum growth. Bone is a dynamic tissue. It undergoes a continuous process of formation and **resorption**, or destruction, at equal rates until the age of 35 years. In later years, bone resorption increases, decreasing bone mass and predisposing patients to injury, especially older women.

Numerous minerals and hormones affect bone growth and metabolism, including:

- Calcium
- Phosphorus
- Calcitonin
- Vitamin D
- Parathyroid hormone (PTH)
- Growth hormone
- Glucocorticoids
- Estrogens and androgens
- Thyroxine
- Insulin

Bone accounts for about 99% of the *calcium* in the body and 90% of the *phosphorus*. In healthy adults, the serum concentrations of calcium and phosphorus maintain an inverse relationship. As calcium levels rise, phosphorus levels decrease. When serum levels are altered, calcitonin and PTH work to maintain equilibrium. If the calcium in the blood is decreased, the bone, which stores calcium, releases calcium into the bloodstream in response to PTH stimulation.

Calcitonin is produced by the thyroid gland and *decreases* the serum calcium concentration if it is increased above its normal level. Calcitonin inhibits bone resorption and increases renal excretion of calcium and phosphorus as needed to maintain balance in the body.

Vitamin D and its metabolites are produced in the body and transported in the blood to promote the absorption of calcium and phosphorus from the small intestine. They also seem to enhance PTH activity to release calcium from the bone. A decrease in the body's vitamin D level can result in osteomalacia (softening of bone) in the adult. Vitamin D metabolism and osteomalacia are described in [Chapter 53](#).

When serum calcium levels are lowered, *parathyroid hormone* (PTH, or parathormone) secretion increases and stimulates bone to promote osteoclastic activity and *release* calcium to the blood. PTH reduces the renal excretion of

calcium and facilitates its absorption from the intestine. If serum calcium levels increase, PTH secretion diminishes to preserve the bone calcium supply. This process is an example of the feedback loop system of the endocrine system.

Growth hormone secreted by the anterior lobe of the pituitary gland is responsible for increasing bone length and determining the amount of bone matrix formed before puberty. During childhood, an increased secretion results in gigantism and a decreased secretion results in dwarfism. In the adult, an increase causes acromegaly, which is characterized by bone and soft-tissue deformities (see [Chapter 65](#)).

Adrenal glucocorticoids regulate protein metabolism, either increasing or decreasing catabolism to reduce or intensify the organic matrix of bone. They also aid in regulating intestinal calcium and phosphorus absorption.

Estrogens stimulate osteoblastic (bone-building) activity and inhibit PTH. When estrogen levels decline at menopause, women are susceptible to low serum calcium levels with increased bone loss (osteoporosis). *Androgens*, such as testosterone in men, promote anabolism (body tissue building) and increase bone mass.

Thyroxine is one of the principal hormones secreted by the thyroid gland. Its primary function is to increase the rate of protein synthesis in all types of tissue, including bone. *Insulin* works together with growth hormone to build and maintain healthy bone tissue.

Joints

A **joint** is a space in which two or more bones come together. This is also referred to as *articulation* of the joint. The major function of a joint is to provide movement and flexibility in the body.

There are three types of joints in the body:

- Synarthrodial, or completely immovable, joints (e.g., in the cranium)
- Amphiarthrodial, or slightly movable, joints (e.g., in the pelvis)
- Diarthrodial (synovial), or freely movable, joints (e.g., the elbow and knee)

Although any of these joints can be affected by disease or injury, the synovial joints are most commonly involved.

The diarthrodial, or synovial, joint is the most common type of joint in the body. **Synovial joints** are the only type lined with synovium, a membrane that secretes synovial fluid for lubrication and shock absorption. As shown in [Fig. 52-2](#), the synovium lines the internal portion of the joint capsule but does not normally extend onto the surface of the cartilage at the spongy bone ends. Articular cartilage consists of a collagen fiber matrix impregnated with a complex ground substance. Patients with inflammatory types of arthritis often have synovitis (synovial inflammation) and breakdown of the cartilage. **Bursae**, small sacs lined with synovial membrane, are located at joints and bony prominences to prevent friction between bone and structures adjacent to bone. These structures can also become inflamed, causing bursitis.

Synovial joints are described by their anatomic structures. *Ball-and-socket* joints (shoulder, hip) permit movement in any direction. *Hinge* joints (elbow) allow motion in one plane—flexion and extension. The knee is often classified as a hinge joint, but it rotates slightly, as well as flexes and extends. It is best described as a *condylar* type of synovial

FIG. 52-2 The structure of a synovial joint. Synovium lines the joint capsule but does not extend into the articular cartilage.

joint. The gliding movement of the wrist is characteristic of the *biaxial* joint. *Pivot* joints permit rotation only, as in the radioulnar area.

Muscular System

There are three types of muscle in the body: smooth muscle, cardiac muscle, and skeletal muscle. Smooth, or non-striated, involuntary muscle is responsible for contractions of organs and blood vessels and is controlled by the autonomic nervous system. Cardiac muscle, or striated, involuntary muscle, is also controlled by the autonomic nervous system. The smooth and cardiac muscles are discussed with the body systems to which they belong in the assessment chapters.

In contrast to smooth and cardiac muscle, skeletal muscle is striated, voluntary muscle controlled by the central and peripheral nervous systems. The junction of a peripheral motor nerve and the muscle cells that it supplies is sometimes referred to as a **motor end plate**. Muscle fibers are held in place by connective tissue in bundles, or fasciculi. The entire muscle is surrounded by dense fibrous tissue, or fascia, which contains the muscle's blood, lymph, and nerve supply.

The main function of skeletal muscle is *movement* of the body and its parts. When bones, joints, and supporting structures are adversely affected by injury or disease, the adjacent muscle tissue is often involved, limiting mobility. During the aging process, muscle fibers decrease in size and number, even in well-conditioned adults. Atrophy results when muscles are not regularly exercised and they deteriorate from disuse.

Supporting structures for the muscular system are very susceptible to injury. They include **tendons** (bands of tough, fibrous tissue that attach muscles to bones) and **ligaments**, which attach bones to other bones at joints.

CHART 52-1 NURSING FOCUS ON THE OLDER ADULT

Changes in the Musculoskeletal System Related to Aging

PHYSIOLOGIC CHANGE	NURSING INTERVENTIONS	RATIONALES
Decreased bone density	Teach safety tips to prevent falls. Reinforce need to exercise, especially weight-bearing exercise.	Porous bones are more likely to fracture. Exercise slows bone loss.
Increased bone prominence	Prevent pressure on bone prominences.	There is less soft tissue to prevent skin breakdown.
Kyphotic posture: widened gait, shift in the center of gravity	Teach proper body mechanics; instruct the patient to sit in supportive chairs with arms.	Correction of posture problems prevents further deformity; the patient should have support for bony structures.
Cartilage degeneration	Provide moist heat, such as a shower or warm, moist compresses.	Moist heat increases blood flow to the area.
Decreased range of motion (ROM)	Assess the patient's ability to perform ADLs and mobility.	The patient may need assistance with self-care skills.
Muscle atrophy, decreased strength	Teach isometric exercises.	Exercises increase muscle strength.
Slowed movement	Do not rush the patient; be patient.	The patient may become frustrated if hurried.

MUSCULOSKELETAL CHANGES ASSOCIATED WITH AGING

Osteopenia, or decreased bone density (bone loss), occurs as one ages. Many older adults, especially white, thin women, have severe osteopenia, a disease called *osteoporosis*. This condition causes postural and gait changes and predisposes the person to fractures. [Chapter 53](#) discusses this health problem in detail.

Synovial joint cartilage can become less elastic and compressible as a person ages. As a result of these cartilage changes and continued use of joints, the joint cartilage becomes damaged, leading to osteoarthritis (OA). Genetic defects in cartilage may also contribute to joint disease. The most common joints affected are the weight-bearing joints of the hip, knee, and cervical and lumbar spine, but joints in the shoulder and upper extremity, feet, and hands can be affected. Refer to [Chapter 20](#) for a complete discussion of OA.

As one ages, muscle tissue atrophies. Increased activity and exercise can slow the progression of atrophy and restore muscle strength. Musculoskeletal changes cause decreased coordination, loss of muscle strength, gait changes, and a risk for falls with injury. (See [Chapter 3](#) for discussion on fall prevention.) [Chart 52-1](#) lists the major anatomic and physiologic changes and implications for nursing care.

CHART 52-2 MUSCULOSKELETAL ASSESSMENT

Using Gordon's Functional Health Patterns

Activity-Exercise Pattern

- Do you have sufficient energy for desired/required activities?
- What is your exercise pattern? Type of exercise? Regularity?
- What spare time (leisure) activities do you engage in?
- What is your perceived ability for (code for level according to key below):

Feeding?	Level 0: Full self-care
Bathing?	Level I: Requires use of equipment or device
Toileting?	
Bed mobility?	Level II: Requires assistance of or supervision by another person
Dressing?	
Grooming?	Level III: Requires assistance of or supervision by another person and equipment or device
General mobility?	
Cooking?	
Home maintenance?	Level IV: Is dependent and does not participate
Shopping?	

Cognitive-Perceptual Pattern

- Do you experience any discomfort?
- Do you have pain? If so, how do you manage it?
- What is the easiest way for you to learn things?
- Do you have any difficulty learning?

Based on Gordon, M. (2011). *Manual of nursing diagnosis* (12th ed.). New York: Jones & Bartlett.

ASSESSMENT METHODS

Patient History

In the assessment of a patient with an actual or potential musculoskeletal problem, a detailed and accurate history is helpful in identifying priority problems and nursing interventions (Chart 52-2). The history reveals information about the patient that can direct the physical assessment.

Accidents, illnesses, lifestyle, and drugs may contribute to a patient's current problem. Young men are at the greatest risk for trauma related to motor vehicle crashes. Older adults are at the greatest risk for falls that result in fractures and soft-tissue injury. When taking a personal health history, question the patient about any traumatic injuries and sports activities, no matter when they occurred. An injury to the lumbar spine 30 years ago may have caused a patient's current low back pain. A motor vehicle crash or sports injury can cause osteoarthritis years after the event.

Previous or current illness or disease may affect musculoskeletal status. For example, a patient with diabetes who is treated for a foot ulcer is at high risk for acute or chronic osteomyelitis (bone infection). In addition, diabetes slows the healing process. Ask the patient about any previous hospitalizations and illnesses or complications. Inquire about his or her ability to perform ADLs independently or if assistive/adaptive devices are used.

Current lifestyle also contributes to musculoskeletal health. Weight-bearing activities such as walking can reduce risk factors for osteoporosis and maintain muscle strength. High-impact sports, such as excessive jogging or running, can cause musculoskeletal injury to soft tissues and bone. Tobacco use slows the healing of musculoskeletal injuries. Excessive

alcohol intake can decrease vitamins and nutrients the person needs for bone and muscle tissue growth.

When assessing a patient with a possible musculoskeletal alteration, inquire about occupation or work life. A person's occupation can cause or contribute to an injury. For instance, fractures are not uncommon in patients whose jobs require manual labor, such as housekeepers, mechanics, and industrial workers. Certain occupations, such as computer-related jobs, may predispose a person to carpal tunnel syndrome (entrapment of the median nerve in the wrist) or neck pain. Construction workers and health care workers may experience back injury from prolonged standing and excessive lifting. Amateur and professional athletes often experience acute musculoskeletal injuries (e.g., joint dislocations and fractures) and chronic disorders (e.g., joint cartilage trauma), which can lead to osteoarthritis.

Ask about allergies, particularly allergy to dairy products, and previous and current use of drugs—prescribed, over-the-counter, and illicit. Allergy to dairy products could cause decreased calcium intake. Some drugs, such as steroids, can negatively affect calcium metabolism and promote bone loss. Other drugs may be taken to relieve musculoskeletal pain. Inquire about herbs, vitamin and mineral supplements, or biologic compounds that may be used for arthritis and other musculoskeletal problems, such as glucosamine and chondroitin. Complementary and alternative therapies are commonly used by patients with various types of arthritis and **arthralgias** (joint aching).

Nutrition History

A brief review of the patient's nutrition history helps determine any risks for inadequate nutrient intake. For example, most people, especially women, do not get enough calcium in their diet. Determine if the patient has had a significant weight gain or loss.

Ask the patient to recall a typical day of food intake to help identify deficiencies and excesses in the diet. Lactose intolerance is a common problem that can cause inadequate calcium intake. People who cannot afford to buy food are especially at risk for undernutrition. Some older adults and others are not financially able to buy the proper foods for adequate nutrition.

Inadequate protein or insufficient vitamin C or D in the diet slows bone and tissue healing. Obesity places excess stress and strain on bones and joints, with resulting fractures and trauma to joint cartilage. In addition, obesity inhibits mobility in patients with musculoskeletal problems, which predisposes them to complications such as respiratory and circulatory problems. People with eating disorders such as anorexia nervosa and bulimia nervosa are also at risk for osteoporosis related to decreased intake of calcium and vitamin D.

Family History and Genetic Risk

Obtaining a family history assists in identifying disorders that have a familial or genetic tendency. Osteoporosis (age-related bone loss) and gout, for instance, often occur in several generations of a family. Osteogenic sarcoma, a type of bone cancer, may be genetically influenced by *Tp53* gene mutation (Nussbaum et al., 2007). Positive family history of these types of disorders can increase risks to the patient. **Chapters 20 and**

53 provide a more complete description of musculoskeletal problems that have strong genetic links.

Current Health Problems

The most common reports of persons with a musculoskeletal problem are pain and weakness, either of which can impair mobility. Collect data pertinent to the patient's presenting health problem as follows:

- Date and time of onset
- Factors that cause or exacerbate (worsen) the problem
- Course of the problem (e.g., intermittent or continuous)
- Clinical manifestations (as expressed by the patient) and the pattern of their occurrence
- Measures that improve clinical manifestations (e.g., heat, ice)

Assessment of pain can present many challenges. Pain can be related to bone, muscle, or joint problems. *Pain* may be described as acute or chronic, depending on the onset and duration. Pain with movement could indicate a fracture and/or muscle or joint injury. Assess the intensity of pain by using a pain scale and asking the patient to rate the level of pain he or she is experiencing. Quality of pain may be described as dull, burning, aching, or stabbing. Determine the location of pain and areas to which the pain may radiate. With any pain assessment, it is always best if the patient describes the pain in his or her own words and points to its location, if possible.

Weakness may be related to individual muscles or muscle groups. Determine if weakness occurs in proximal or distal muscles or muscle groups. Proximal weakness may indicate **myopathy** (a problem in muscle tissue), whereas distal weakness may indicate **neuropathy** (a problem in nerve tissue). Muscle weakness in the lower extremities may increase the risk for falls and injury. Weakness in the upper extremities may interfere with ADLs.

Assessment of the Skeletal System

Although bones, joints, and muscles are usually assessed simultaneously in a head-to-toe approach, each subsystem is described separately for emphasis and understanding. For physical assessment of the musculoskeletal system, use inspection, palpation, and range of motion (ROM). A general assessment is described in this chapter. More specific assessment techniques are discussed in the musculoskeletal problem chapters in this unit.

General Inspection

Observe the patient's posture, gait, and general mobility for gross deformities and impairment. Note unusual findings, and coordinate with the physical or occupational therapist for an in-depth physical assessment.

Posture and Gait. *Posture* includes the person's body build and alignment when standing and walking. Assess the curvature of the spine and the length, shape, and symmetry of extremities. Fig. 52-3 illustrates several common spinal deformities. Inspect muscle mass for size and symmetry.

Most patients with musculoskeletal problems eventually have a problem with *gait*. The nurse or therapist evaluates the patient's balance, steadiness, and ease and length of stride. Any limp or other asymmetric leg movement or deformity is

FIG. 52-3 Common spinal deformities.

noted. An abnormality in the stance phase of gait is called an **antalgic** gait. When part of one leg is painful, the patient shortens the stance phase on the affected side. An abnormality in the swing phase is called a **lurch**. This abnormal gait occurs when the muscles in the buttocks and/or legs are too weak to allow the person to change weight from one foot to the other. In this case, the shoulders are moved either side-to-side or front-to-back for help in shifting the weight from one leg to the other. Some patients, such as those with chronic hip pain and muscle atrophy from arthritic disorders, have a combination of an antalgic gait and lurch.

Mobility and Functional Assessment. In collaboration with the physical or occupational therapist, assess the patient's need for ambulatory devices, such as canes and walkers, during transfer from bed to chair and while walking and climbing stairs. Observe his or her ability to perform ADLs, such as dressing and bathing (see Chart 52-2). Pain and deformity may limit physical mobility and function. Coordinate with the physical and occupational therapists to assess the patient's functional status. A complete discussion of functional assessment is found in Chapter 8.

Assess major bones, joints, and muscles by inspection, palpation, and determination of ROM. Pay special attention to areas that are affected or may be affected, according to the patient's history or current problem.

A **goniometer** is a tool that may be used by rehabilitation therapists or nurses to provide an exact measurement of flexion and extension or joint ROM. Active range of motion (AROM) can be evaluated by asking the patient to move each joint through the ROM himself or herself. If the patient cannot actively move a joint through range of motion, ask him or her to relax the muscles in the extremity. Hold the part with one hand above and one hand below the joint to be evaluated and allow passive range of motion (PROM) to evaluate joint mobility. Movements shown in Fig. 52-4 may be used to evaluate active and passive ROM. Circumduction is a movement that can also be evaluated in the shoulder by having the patient move the arm in circles from the shoulder joint. As long as the patient can function to meet personal

FIG. 52-4 Movements of the skeletal muscles.

needs, a limitation in ROM may not be significant. For each anatomic location, observe the skin for color, elasticity, and lesions that may relate to musculoskeletal dysfunction. For instance, redness or warmth may indicate an inflammatory process and/or pressure injury to skin.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

A nurse is performing a musculoskeletal assessment on an older adult. What physiologic changes of aging will the nurse expect?

Select all that apply.

- A. Scoliosis
- B. Muscle atrophy
- C. Slowed movement
- D. Rheumatoid arthritis
- E. Antalgic gait

Specific Assessments

If the patient has pain or weakness in the *face* or *neck*, inspect and palpate this area for tenderness and masses. Ask the patient to open his or her mouth while palpating the temporomandibular joints (TMJs). Common abnormal findings are tenderness or pain, **crepitus** (a grating sound), and a spongy swelling caused by excess synovium and fluid.

Inspect and palpate each vertebra of the spine in the neck. Proceed cautiously and gently if pain is present. Clinical

findings may include malalignment; tenderness; or inability to flex, extend, and rotate the neck as expected. Muscle and nerve pain often accompany neck pain if spinal nerves are involved.

The thoracic *spine*, lumbar spine, and sacral spine are evaluated in the same manner as the neck. Spinal alignment problems are common (see Fig. 52-3). Place both hands over the posterior iliac crests with the thumbs over the lumbosacral area. Apply pressure with the thumbs along the lumbosacral spine to elicit tenderness. Many patients do not have discomfort until the area is palpated. **Lordosis** is a common finding in adults who have abdominal obesity. During screening for **scoliosis**, ask the patient to flex forward from the hips and inspect for a lateral curve in the spine.

If the extremities are affected by a musculoskeletal problem, assess arms or legs at the same time for side-to-side comparisons. For example, inspect and palpate both shoulders for size, swelling, deformity, poor alignment, tenderness or pain, and mobility. A shoulder injury may prevent the patient from combing his or her hair with the affected arm, but severe arthritis may inhibit movement in both arms. Assess the elbows and wrists in a similar way.

Because the hand has multiple joints in a single digit, assessment of hand function is perhaps the most critical part of the examination. If the hands are affected, inspect and palpate the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and distal interphalangeal (DIP) joints. The

FIG. 52-5 The small joints of the hand.

same digits are compared on the right and left hands (Fig. 52-5). Determine the range of motion (ROM) for each joint by observing active movement. If movement is not possible, evaluate passive motion. For a quick and easy assessment of ROM, ask the patient to make a fist and then appose each finger to the thumb. If he or she can perform these maneuvers, ROM of the hand is not seriously restricted.

Evaluation of the hip joint relies primarily on determination of its degree of mobility, because the joint is deep and difficult to inspect or palpate. The patient with hip pain usually experiences it in the *groin* or has pain that radiates to the knee. The knee is readily accessible for physical assessment, particularly when the patient is sitting and the knee is flexed. Fluid accumulation, or **effusion**, is easily detected in the knee joint. Limitations in movement with accompanying pain are common findings. The knees may be poorly aligned, as in **genu valgum** (“knock-knee”) or **genu varum** (“bow-legged”) deformities.

The ankles and feet are often neglected in the physical examination. However, they contain multiple bones and joints that can be affected by disease and injury. Observe and palpate each joint and test for ROM if feet are affected by musculoskeletal problems.

Neurovascular Assessment

While completing a physical assessment of the musculoskeletal system, perform an assessment of peripheral vascular and nerve integrity. Beginning with the injured side, always compare one extremity with the other.

TABLE 52-2 LOVETT'S SCALE FOR GRADING MUSCLE STRENGTH

RATING	DESCRIPTION
5	Normal: ROM unimpaired against gravity with full resistance
4	Good: can complete ROM against gravity with some resistance
3	Fair: can complete ROM against gravity
2	Poor: can complete ROM with gravity eliminated
1	Trace: no joint motion and slight evidence of muscle contractility
0	Zero: no evidence of muscle contractility

ROM, Range of motion.

NURSING SAFETY PRIORITY

Action Alert

Perform a complete **neurovascular assessment** (also called a “circ” check), which includes *palpation of pulses in the extremities below the level of injury and assessment of sensation, movement, color, temperature, and pain in the injured part*. If pulses are not palpable, use a Doppler to find pulses in the extremities. See [Chart 54-3](#) in [Chapter 54](#) for more details about neurovascular assessment.

Assessment of the Muscular System

During the skeletal assessment, notice the size, shape, tone, and strength of major skeletal muscles. The circumference of each muscle may be measured and compared symmetrically for an estimation of muscle mass if abnormalities are observed.

Ask the patient to demonstrate muscle strength. Apply resistance by holding the extremity and asking the patient to move against resistance. As an option, place your hands on the patient's upper arms and ask the patient to try to raise the arms. Although movement against resistance is not easily quantified, several scales used by nurses and therapists are available for grading the patient's strength. A commonly used scale is shown in [Table 52-2](#).

Psychosocial Assessment

The data from the history and physical assessment provide clues for anticipating psychosocial problems. For instance, prolonged absence from employment or permanent disability may cause job or career loss. Further stress may be experienced if chronic pain continues and the patient cannot cope with numerous stressors. Anxiety and depression are common when patients have chronic pain. Deformities resulting from musculoskeletal disease or injury, such as an amputation, can affect a person's body image and self-concept. Help the patient identify support systems and coping mechanisms that may be useful if he or she has long-term musculoskeletal health problems. Encourage him or her to verbalize feelings related to loss and body image changes. Refer the patient for psychological or spiritual counseling if needed and if it is culturally appropriate.

Diagnostic Assessment

Laboratory Assessment

[Chart 52-3](#) lists the common laboratory tests used in assessing patients with musculoskeletal disorders. There is no special patient preparation or follow-up care for any of these

CHART 52-3 LABORATORY PROFILE

Musculoskeletal Assessment

TEST	NORMAL RANGE FOR ADULTS	SIGNIFICANCE OF ABNORMAL FINDINGS
Serum calcium	9.0-10.5 mg/dL (2.25-2.75 mmol/L) <i>Older adults:</i> decreased	<i>Hypercalcemia</i> (increased calcium) - Metastatic cancers of the bone - Paget's disease - Bone fractures in healing stage <i>Hypocalcemia</i> (decreased calcium) - Osteoporosis - Osteomalacia
Serum phosphorus	3.0-4.5 mg/dL (0.97-1.45 mmol/L) <i>Older adults:</i> decreased	<i>Hyperphosphatemia</i> (increased phosphorus) - Bone fractures in healing stage - Bone tumors - Acromegaly <i>Hypophosphatemia</i> (decreased phosphorus) - Osteomalacia
Alkaline phosphatase (ALP)	30-120 units/L <i>Older adults:</i> slightly increased	<i>Elevations</i> may indicate: - Metastatic cancers of the bone - Paget's disease - Osteomalacia
Serum muscle enzymes Creatine kinase (CK-MM)	Total CK: <i>Men:</i> 55-170 units/L <i>Women:</i> 30-135 units/L	<i>Elevations</i> may indicate: - Muscle trauma - Progressive muscular dystrophy - Effects of electromyography
Lactic dehydrogenase (LDH)	Total LDH: 100-190 units/L <i>LDH₁:</i> 17%-27% <i>LDH₂:</i> 27%-37% <i>LDH₃:</i> 18%-25% <i>LDH₄:</i> 3%-8% <i>LDH₅:</i> 0% to 5%	<i>Elevations</i> may indicate: - Skeletal muscle necrosis - Extensive cancer - Progressive muscular dystrophy
Aspartate aminotransferase (AST)	0-35 units/L <i>Older adults:</i> increased	<i>Elevations</i> may indicate: - Skeletal muscle trauma - Progressive muscular dystrophy
Aldolase (ALD)	3.0-8.2 units/dL	<i>Elevations</i> may indicate: - Polymyositis and dermatomyositis - Muscular dystrophy

tests. Teach the patient about the purpose of the test and the procedure that can be expected. Additional tests performed for patients with connective tissue diseases, such as rheumatoid arthritis, are described in [Chapter 20](#).

Disorders of bone and the parathyroid gland are often reflected in an alteration of the serum calcium or phosphorus level. Therefore these electrolytes, especially calcium, are monitored.

Alkaline phosphatase (ALP) is an enzyme normally present in blood. The concentration of ALP increases with bone or liver damage. In metabolic bone disease and bone cancer, the enzyme concentration rises in proportion to the osteoblastic activity, which indicates bone formation. The level of ALP is normally slightly increased in older adults.

The major *muscle enzymes* affected in skeletal muscle disease or injuries are:

- Creatine kinase (CK-MM)
- Aspartate aminotransferase (AST)
- Aldolase (ALD)
- Lactic dehydrogenase (LDH)

As a result of damage, the muscle tissue releases additional amounts of these enzymes, which increases serum levels.

The serum CK level begins to rise 2 to 4 hours after muscle injury and is elevated early in muscle disease, such as muscular dystrophy. The CK molecule has two subunits: M (muscle) and B (brain). Three isoenzymes have been identified. Skeletal muscle CK (CK-MM, or CK₃) is the only isoenzyme that rises in concentration with damage to skeletal muscle, such as trauma, surgery, and neuromuscular disease. This test is 90% accurate because it is affected by exercise and certain drugs, such as anticoagulants, furosemide, and statins (Kress et al., 2008).

AST is moderately elevated (three to five times normal) in certain muscle diseases, such as muscular dystrophy. The levels of the isoenzymes aldolase A (ALD-A) and LDH₅ also increase in patients with these disorders.

Imaging Assessment

The skeleton is very visible on *standard x-rays*. Anteroposterior and lateral projections are the initial screening views used most often. Other approaches, such as oblique or stress views, depend on the part of the skeleton to be evaluated and the necessity of the x-ray.

Bone density, alignment, swelling, and intactness can be seen on x-ray. The conditions of joints can be determined,

including the size of the joint space, the smoothness of articular cartilage, and synovial swelling. Soft-tissue involvement may be evident but not clearly differentiated.

Inform the patient that the x-ray table is hard and cold, and instruct him or her to remain still during the filming process. Coordinate with the radiology department or clinic to keep older adults and those at risk for hypothermia as warm as possible (e.g., by using blankets).

Whereas standard x-rays superimpose one structure on another, **tomography** produces planes, or slices, for focus and blurs the images of other structures. This procedure is helpful in detailing the musculoskeletal system, because the many close structures make visualization difficult.

Xeroradiography highlights the contrast between structures. Margins and edges can be clearly seen (edge enhancement). Disadvantages of xeroradiography are the higher radiation dose to the patient and inability of the test to determine tissue densities.

Myelography involves the injection of contrast medium into the subarachnoid space of the spine, usually by spinal puncture. The vertebral column, intervertebral disks, spinal nerve roots, and blood vessels can be visualized. Although this test is still performed, it is far less popular. Computed tomography (CT) and magnetic resonance imaging (MRI) have often replaced such invasive and potentially painful and risky diagnostic techniques. The post-test care is similar to that for lumbar puncture, except that the patient is usually placed with the head of the bed elevated 30 to 50 degrees to prevent the contrast medium from getting into the brain (see Chapter 43).

An **arthrogram** is an x-ray study of a joint after contrast medium (air or solution) has been injected to enhance its visualization. Double-contrast arthrography, which uses both air and contrast, may be performed when a traumatic injury is suspected. The physician can often determine bone chips, torn ligaments, or other loose bodies within the joint. This test is not used commonly because of newer advances in diagnostic imaging. Most joints are now studied by MRI.

Computed tomography (CT) has gained wide acceptance for detecting musculoskeletal problems, particularly those of the vertebral column and joints. The scanned images can be used to create additional images from other angles or to create three-dimensional images and view complex structures from any position. The nurse or radiology technologist should ask the patient about iodine-based contrast allergies.

Nuclear Scans. The **bone scan** is a radionuclide test in which radioactive material is injected for viewing the entire skeleton. It may be used primarily to detect tumors, arthritis, osteomyelitis, osteoporosis, vertebral compression fractures, and unexplained bone pain. Bone scans are used less commonly today as more sophisticated MRI equipment becomes more available. However, it may be very useful for detecting hairline fractures in patients with unexplained bone pain and diffuse metastatic bone disease.

The **gallium** and **thallium scans** are similar to the bone scan but are more specific and sensitive in detecting bone problems. Gallium citrate (^{67}Ga) is the radioisotope most commonly used. This substance also migrates to brain, liver, and breast tissue and therefore is used in examination of these structures when disease is suspected.

For patients with osteosarcoma, thallium (^{201}Tl) is better than gallium or technetium for diagnosing the extent of the

disease. Thallium has traditionally been used for the diagnosis of myocardial infarctions but can be used for additional evaluation of cancers of the bone.

Because bone takes up gallium slowly, the nuclear medicine physician or technician administers the isotope 4 to 6 hours before scanning. Other tests that require contrast media or other isotopes cannot be given during this time.

Instruct the patient that the radioactive material poses no threat because it readily deteriorates in the body. Because gallium is excreted through the intestinal tract, it tends to collect in feces after the scanning procedure.

Depending on the tissue to be examined, the patient is taken to the nuclear medicine department 4 to 6 hours after injection. The procedure takes 30 to 60 minutes, during which time the patient must lie still for accurate test results to be achieved. The scan may be repeated at 24, 48, and/or 72 hours. Mild sedation may be necessary to facilitate relaxation and cooperation during the procedure for confused older adults or those in severe pain.

No special care is required after the test. The radioisotope is excreted in stool and urine, but no precautions are taken in handling the excreta. Remind the patient to push fluids to facilitate urinary excretion.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI), with or without the use of contrast media, is commonly used to diagnose musculoskeletal disorders. It is more accurate than computed tomography (CT) and myelography for many spinal and knee problems. MRI is most appropriate for joints, soft tissue, and bony tumors that involve soft tissue. CT is still the test of choice for injuries or pathology that involves only bone.

The image is produced through the interaction of magnetic fields, radio waves, and atomic nuclei showing hydrogen density. Simply put, the radio waves “bounce” off the body tissues being examined. Because each tissue has its own density, the computer image clearly distinguishes normal and abnormal tissues. For some tissues, the cross-sectional image is better than that produced by radiography or CT. The lack of hydrogen ions in cortical bone makes it easily distinguishable from soft tissues. The test is particularly useful in identifying problems with muscles, tendons, and ligaments.

Ensure that the patient removes all metal objects and checks for clothing zippers and metal fasteners. Although joint implants made of titanium or stainless steel are usually safe, depending on the age of the MRI equipment, pacemakers, stents, and surgical clips usually are not. **Chart 52-4** lists questions that the nurse or technician should consider in preparing the patient for MRI. Open MRIs prevent the claustrophobia that occurs with the older, encased machines.

Ultrasonography. Sound waves produce an image of the tissue in ultrasonography. An ultrasound procedure may be used to view:

- Soft-tissue disorders, such as masses and fluid accumulation
- Traumatic joint injuries
- Osteomyelitis
- Surgical hardware placement

A jelly-like substance applied to the skin over the site to be examined promotes the movement of a metal probe. No special preparation or post-test care is necessary. A quantitative ultrasound (QUS) may be done for determining fractures or bone density.

CHART 52-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Preparing the Patient for Magnetic Resonance Imaging

- Is the patient pregnant?
- Does the patient have ferromagnetic fragments or implants, such as an older-style aneurysm clip?
- Does the patient have a pacemaker, stent, or electronic implant?
- Does the patient have chronic kidney disease? (Gadolinium contrast agents may cause severe systemic complications if the kidneys do not function.)
- Can the patient lie still in the supine position for 45 to 60 minutes? (May require sedation.)
- Does the patient need life-support equipment available?
- Can the patient communicate clearly and understand verbal communication?
- Did the patient get any tattoo *more than 20 years ago*? (If so, metal particles *may* be in the ink.)
- Is the patient claustrophobic? (Ask this question for closed MRI scanners; open MRIs do not cause claustrophobia.)

Other Diagnostic Assessment

Biopsies. In a **bone biopsy**, the physician extracts a specimen of the bone tissue for microscopic examination. This invasive test may confirm the presence of infection or neoplasm, but it is not commonly done today. One of two techniques may be used to retrieve the specimen: needle (closed) biopsy or incisional (open) biopsy. It is important to watch for bleeding from the puncture site and for tenderness, redness, or warmth that could indicate infection. Mild analgesics may be used.

Muscle biopsy is done for the diagnosis of atrophy (as in muscular dystrophy) and inflammation (as in polymyositis). The procedure and care for patients undergoing muscle biopsy are the same as those for patients undergoing bone biopsy.

Electromyography. Electromyography (EMG) is used to evaluate diffuse or localized muscle weakness. EMG is usually accompanied by nerve conduction studies for determining the electrical potential generated in an individual muscle. EMG helps in the diagnosis of neuromuscular, lower motor neuron, and peripheral nerve disorders. This test is contraindicated for patients undergoing anticoagulant therapy.

Inform the patient that EMG may cause temporary discomfort, especially when the patient is subjected to episodes of electrical current. For selected patients, mild sedation is prescribed. The physician may also prescribe a temporary discontinuation of skeletal muscle relaxants several days before the procedure to prevent drugs from affecting the test results.

The test may be performed at the bedside or in an EMG laboratory. When both EMG and nerve conduction studies are done, nerve conduction is usually tested first. Flat electrodes are placed along the nerve to be evaluated, and low electrical currents are passed through the electrodes to the nerve and muscle innervated. If nerve conduction occurs, the muscle contracts.

For testing muscle potential, multiple small needle electrodes are inserted. The patient is asked to perform activities for measurement of muscle potential during minimal and maximal contraction. The degree of nerve and muscle activity is recorded for later interpretation.

A few medical complications are associated with EMG. The nurse provides comfort measures and inspects the needle sites for hematoma formation. The application of ice can prevent this complication. The patient may also report increased pain and anxiety after the test.

Arthroscopy. The **arthroscopy** may be used as a diagnostic test or a surgical procedure. An arthroscope is a fiberoptic tube inserted into a joint for direct visualization of the ligaments, menisci, and articular surfaces of the joint. The knee and shoulder are most commonly evaluated. In addition, synovial biopsy and surgery to repair traumatic injury can be done through the arthroscope as an ambulatory care procedure.

Patient Preparation. Because the knee is most commonly “scoped,” the care described for the patient undergoing arthroscopy relates to that joint. Arthroscopy is performed on an ambulatory basis or as same-day surgery. The patient must be able to flex the knee. Those who cannot flex the knee at least 40 degrees or who have an infected knee are not candidates for the procedure. If the patient cannot flex the knee, the arthroscope cannot be inserted into the joint space to allow visualization. Joint infection may worsen from the mechanical trauma of arthroscope insertion.

If the procedure is done for surgical repair, the patient may have a physical therapy consultation before arthroscopy to learn the leg exercises that are necessary after the test. Straight-leg raises (SLRs) and quadriceps setting exercises (isometrics with the leg extended) are practiced in sets of 10 each. ROM exercises are also taught but may not be allowed immediately after arthroscopic surgery. The nurse in the surgeon’s office or at the surgical center can teach these exercises or reinforce the information provided by the physical therapist. The nurse also reinforces the explanation of the procedure and post-test care and ensures that the patient has signed an informed consent.

Procedure. The patient is usually given local, light general, or epidural anesthesia, depending on the purpose of the procedure. In some settings, a large pneumatic tourniquet is used around the thigh to minimize bleeding during the procedure. Drugs that promote vasoconstriction for control of bleeding may be used alone or in conjunction with the tourniquet.

The knee is flexed to at least 40 degrees and is irrigated. As shown in Fig. 52-6, the arthroscope is inserted through a small incision less than ¼-inch (0.6 cm) long. Multiple incisions may be required to allow inspection at a variety of angles. After the procedure, a dressing may be applied, depending on the amount of manipulation during the test or surgery.

Postprocedure Care. The immediate care after an arthroscopy is the same for patients having the procedure for diagnostic purposes and those having an arthroscopy for surgical intervention.

! NURSING SAFETY PRIORITY

Action Alert

The priority for postprocedure care after arthroscopy is to assess the neurovascular status of the patient’s affected limb every hour or according to agency or surgeon protocol. Monitor and document distal pulses, warmth, color, capillary refill, pain, movement, and sensation of the affected extremity.

FIG. 52-6 An arthroscope is used in the diagnosis of pathologic changes in the joints. This patient is undergoing arthroscopy of the shoulder.

Encourage the patient to perform exercises as taught before the procedure, if appropriate. For the mild discomfort experienced after the diagnostic arthroscopy, the physician prescribes a mild analgesic, such as acetaminophen (Tylenol, Ace-Tabs 🍁). If postoperative, the patient may

have short-term activity restrictions, depending on the musculoskeletal problem. Ice is often used for 24 hours, and the extremity should be elevated for 12 to 24 hours. When arthroscopic surgery is performed, the health care provider usually prescribes an opioid-analgesic combination, such as oxycodone and acetaminophen (Percocet, Tylox).

Although complications are not common, monitor and teach the patient to observe for:

- Swelling
- Increased joint pain attributable to mechanical injury
- Thrombophlebitis
- Infection

Severe joint or limb pain after discharge may indicate a possible complication. Teach the patient to contact the physician immediately. The surgeon usually sees the patient about 1 week after the procedure to check for complications.

NCLEX EXAMINATION CHALLENGE

Safe and Effective Care Environment

A client returns to PACU after an arthroscopy to repair several knee ligaments. What is the nurse's priority when caring for this client?

- A. Take vital signs every hour.
- B. Check for swelling and bleeding.
- C. Perform frequent neurovascular assessments.
- D. Ensure that the surgical dressing is intact.

NURSING CONCEPT REVIEW

What should you NOTICE in a patient with adequate mobility and sensation related to the musculoskeletal system?

Physical Assessment

- No gross deformities or impairments in posture or gait
- Adequate size, strength, and symmetry of muscle for age
- Can perform ADLs independently
- Can perform other routine daily activities independently
- Can ambulate with or without assistive devices
- No pain or tenderness on palpation or passive range-of-motion (ROM) of joints

- Active ROM of joints within normal limits for age
- No crepitus when moving joints
- No swelling of joints or extremities
- Equal size and alignment of extremities
- Equal sensation in extremities

Diagnostic Assessment

- Muscle enzymes (e.g., CK-MM, ALD) within normal limits for age
- Bone density adequate for age and gender
- Joint changes within normal limits for age

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Collaborate with the physical and/or occupational therapist to perform a complete musculoskeletal assessment if indicated.

Health Promotion and Maintenance

- Be aware that older adults have physiologic changes that affect their musculoskeletal system (see [Chart 52-1](#)).

Psychosocial Integrity

- Assess the patient's support systems and coping mechanisms when musculoskeletal trauma or disease affects his or her body image.

GET READY FOR THE NCLEX® EXAMINATION! —cont'd

- Ask about the patient's occupation, because heavy manual labor may cause back injury and other musculoskeletal trauma.

Physiological Integrity

- Assess the patient's pain intensity, quality, duration, and location.
- Assess the patient's mobility, including gait, posture, and muscle strength.
- Assess for musculoskeletal changes associated with aging (see [Chart 52-1](#)).
- Interpret the patient's laboratory values that are related to musculoskeletal disease (see [Chart 52-3](#)).
- Teach the patient that mild discomfort can be expected during electromyography, a test to assess the electrical potential of muscles and their innervation.
- Instruct the patient to report swelling, infection, and increased pain after an arthroscopy.
- Ask the patient questions to ensure safety before an MRI (see [Chart 52-4](#)).
- Ask the patient about allergy to contrast media before diagnostic testing such as CT scans.
- Evaluate the neurovascular status of the patient's affected extremity after an arthroscopic procedure as the *priority for care*.

Care of Patients with Musculoskeletal Problems

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Coordinate with health care team members when planning and providing care for patients with musculoskeletal problems.
2. Teach the patient and family about home safety when the patient has a metabolic bone problem such as osteoporosis.
3. Identify community resources for patients with musculoskeletal problems that impair mobility.
4. Apply principles of infection control for patients with osteomyelitis, including Contact Precautions if needed.

Health Promotion and Maintenance

5. Develop a teaching plan for all age-groups about ways to decrease the risk for osteoporosis.
6. Perform health risk assessments for people at risk for osteoporosis and osteomalacia.
7. Assess the genetic risk for patients who have parents with muscular dystrophy.
8. Refer patients with genetic-associated diseases for genetic counseling and testing.

Psychosocial Integrity

9. Assess the patient's and family's responses to a bone cancer diagnosis and treatment options.
10. Evaluate patient's and family's coping strategies and fears related to grief and loss before and after bone cancer surgery.

Physiological Integrity

11. Educate the patient and family about common drugs used for bone diseases, such as calcium supplements and bisphosphonates.
12. Compare and contrast osteoporosis and osteomalacia.
13. Identify key features of Paget's disease of the bone.
14. Differentiate acute and chronic osteomyelitis.
15. Prioritize care for patients with osteomyelitis.
16. Identify collaborative management options for treating patients with primary and metastatic bone cancer.
17. Describe common disorders of the foot, including hallux valgus and plantar fasciitis, that can affect mobility.
18. Explain the role of the nurse when caring for an adult patient with muscular dystrophy.

Musculoskeletal disorders include metabolic bone diseases, such as osteoporosis and Paget's disease, bone tumors, and a variety of deformities and syndromes. Older adults are at the greatest risk for most of these problems, although primary bone cancer is most often found in adolescents and young adults. As technologic advances occur and patients survive

longer with primary cancers, metastatic lesions have become more prevalent among older adults. Almost all musculoskeletal health problems can cause the patient to have difficulty meeting the human need of *mobility*. This chapter focuses on selected disorders not covered in [Chapter 20](#) on arthritis and other connective tissue diseases.

METABOLIC BONE DISEASES

OSTEOPOROSIS

Pathophysiology

Osteoporosis is a chronic metabolic disease in which bone loss causes decreased density and possible fracture. It is often referred to as a “silent disease” because the first sign of osteoporosis in most people follows some kind of a fracture. The spine, hip, and wrist are most often at risk, although any bone can fracture (National Osteoporosis Foundation, 2010).

Osteoporosis is a major health problem in the world. The estimated cost for osteoporosis-related health care alone in the United States is more than \$18 billion each year with continual cost increases each year. By 2040, that number is expected to double or triple (National Osteoporosis Foundation, 2010).

Bone is a dynamic tissue that is constantly undergoing changes in a process referred to as **bone remodeling**. Osteoporosis and **osteopenia** (low bone mass) occur when osteoclastic (bone resorption) activity is greater than osteoblastic (bone building) activity. The result is a decreased **bone mineral density (BMD)**. BMD determines bone strength and peaks between 25 and 30 years of age. Before and during the peak years, osteoclastic activity and osteoblastic activity work at the same rate. After the peak years, bone resorption activity exceeds bone-building activity, and bone density decreases. BMD decreases most rapidly in postmenopausal women as serum estrogen levels diminish. Although estrogen does not build bone, it helps prevent bone loss. **Trabecular**, or **cancelous** (spongy), bone is lost first, followed by loss of **cortical** (compact) bone. This results in thin, fragile bone tissue that is at risk for fracture.

Standards for the diagnosis of osteoporosis are based on BMD testing that provides a T-score for the patient. A T-score represents the number of standard deviations above or below the average BMD for young, healthy adults. *Osteopenia is present when the T-score is at -1 and above -2.5. Osteoporosis is diagnosed in a person who has a T-score at or lower than -2.5.* Medicare reimburses for BMD testing every 2 years in people ages 65 years and older who (National Osteoporosis Foundation, 2010):

- Are estrogen deficient
- Have vertebral abnormalities
- Receive long-term steroid therapy
- Have primary hyperparathyroidism
- Are being monitored while on osteoporosis drug therapy

Osteoporosis can be classified as generalized or regional. *Generalized* osteoporosis involves many structures in the skeleton and is further divided into two categories, primary and secondary. *Primary* osteoporosis is more common and occurs in postmenopausal women and in men in their seventh or eighth decade of life. Even though men do not experience the rapid bone loss that postmenopausal women have, they do have decreasing levels of testosterone (which builds bone) and altered ability to absorb calcium. This results in a slower loss of bone mass in men, especially those older than 75 years. *Secondary* osteoporosis may result from other medical conditions, such as hyperparathyroidism; long-term drug therapy, such as with corticosteroids; or prolonged immobility, such as that seen with spinal cord injury (Table 53-1). Treatment

TABLE 53-1 CAUSES OF SECONDARY OSTEOPOROSIS

Diseases/Conditions	Drugs (Chronic Use)
• Diabetes mellitus • Hyperthyroidism • Hyperparathyroidism • Cushing's syndrome • Growth hormone deficiency • Metabolic acidosis • Female hypogonadism • Paget's disease • Osteogenesis imperfecta • Rheumatoid arthritis • Prolonged immobilization • Bone cancer • Cirrhosis • HIV/AIDS • Chronic airway limitation	• Corticosteroids • Heparin • Anticonvulsants (phenobarbital, phenytoin) • Ethanol (alcohol) • Drugs that induce hypogonadism (decreased levels of sex hormones) • High levels of thyroid hormone • Cytotoxic agents • Immunosuppressants • Loop diuretics • Aluminum-based antacids

AIDS, Acquired immune deficiency syndrome; HIV, human immune deficiency virus.

CHART 53-1 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessing Risk Factors for Primary Osteoporosis

Assess for:

- Older age in both genders and all races
- Parental history of osteoporosis, especially mother
- History of low-trauma fracture after age 50 years
- Low body weight, thin build
- Chronic low calcium and/or vitamin D intake
- Estrogen or androgen deficiency
- Current smoking (active or passive)
- High alcohol intake (3 or more drinks a day)
- Lack of physical exercise or prolonged immobility

of the secondary type is directed toward the cause of the osteoporosis when possible.

Regional osteoporosis, an example of secondary disease, occurs when a limb is immobilized related to a fracture, injury, or paralysis. Immobility for longer than 8 to 12 weeks can result in this type of osteoporosis. Bone loss also occurs when people spend prolonged time in a gravity-free or weightless environment (e.g., astronauts).

Etiology and Genetic Risk

Primary osteoporosis is caused by a combination of genetic, lifestyle, and environmental factors. Chart 53-1 lists the major factors that contribute to the development of this disease.

Primary osteoporosis most often occurs in women after menopause as a result of decreased estrogen levels. Women lose about 2% of their bone mass every year in the first 5 years after natural or surgical (ovary removal) menopause. For women of any age who do not take estrogen replacement, the risk for osteoporosis increases.

Men also develop osteoporosis after the age of 50 because their testosterone levels decrease. Testosterone is the major sex hormone that builds bone tissue. Men are often underdiagnosed, even when they become older adults. A recent study of almost 1200 men in a VA rehabilitation center showed that screening for osteoporosis had not been conducted. As a result of bone mineral density screening, the researchers found 33 study patients who had osteoporosis and were at

GENETIC/GENOMIC CONSIDERATIONS

The genetic and immune factors that cause osteoporosis are very complex. Strong evidence demonstrates that genetics is a significant factor, with a heritability of 50% to 90% (Chang et al., 2010). Many genetic changes have been identified as possible causative factors, but there is no agreement about which ones are most important or constant in all patients. For example, changes in the vitamin D receptor (*VDR*) gene and calcitonin receptor (*CTR*) gene have been found in some patients with the disease. Receptors are essential for the uptake and use of these substances by the cells.

The bone morphogenetic protein-2 (*BMP-2*) gene has a key role in bone formation and maintenance. Some osteoporotic patients who have had fractures have changes in their *BMP-2* gene. Alterations in growth hormone-1 (*GH-1*) have been discovered in petite Asian-American women, those who are predisposed to developing osteoporosis.

Hormones, tumor necrosis factor (TNF), interleukins, and other substances in the body help control osteoclasts in a very complex pathway. The recent identification of the importance of the cytokine receptor activator of nuclear factor kappa-B ligand (*RANKL*), its receptor *RANK*, and its decoy receptor osteoprotegerin (*OPG*) has helped researchers understand more about the activity of osteoclasts in metabolic bone disease. Disruptions in the *RANKL*, *RANK*, and *OPG* system can lead to increased osteoclast activity in which bone is rapidly broken down (McCance et al., 2010).

high risk for fractures, especially of the hip. Those who were diagnosed with the disease were the oldest patients who had a lower body mass index and weight (Swislocki et al., 2010).

Body build and weight seems to influence who gets the disease. Osteoporosis occurs most often in older, lean-built Euro-American and Asian women, particularly those who do not exercise regularly. However, African Americans are at risk for decreased vitamin D, which is needed for adequate calcium absorption in the small intestines. Obese women can store estrogen in their tissues for use as necessary to maintain a normal level of serum calcium. Weight-bearing exercise reduces bone resorption (loss) and stimulates bone formation. Prolonged immobility produces rapid bone loss.

The relationship of osteoporosis to nutrition is well established. For example, excessive caffeine in the diet can cause calcium loss in the urine. A diet lacking enough calcium and vitamin D stimulates the parathyroid gland to produce parathyroid hormone (PTH). PTH triggers the release of calcium from the bony matrix. Activated vitamin D is needed for calcium uptake in the body. Malabsorption of nutrients in the GI tract also contributes to low serum calcium levels. Institutionalized or homebound patients who are not exposed to sunlight may be at a higher risk because they do not receive adequate vitamin D for the metabolism of calcium.

Calcium loss occurs at a more rapid rate when phosphorus intake is high. (Chapter 13 describes the usual relationship between calcium and phosphorus in the body.) People who drink large amounts of carbonated beverages each day (over 40 ounces) are at high risk for calcium loss and subsequent osteoporosis, regardless of age or gender.

Protein deficiency may also reduce bone density. Because 50% of serum calcium is protein bound, protein is needed to use calcium. However, excessive protein intake may increase calcium loss in the urine. For instance, people who are on high-protein, low-carbohydrate diets, like the Atkins diet, may consume too much protein to replace other food not allowed. Dietary protein intake in healthy adults is

recommended at 0.8 grams per kilogram of body weight. Protein is needed for bone healing when a fracture occurs.

Excessive alcohol and tobacco use are other risk factors for osteoporosis. Although the exact mechanisms are not known, these substances promote acidosis, which in turn increases bone loss. Alcohol also has a direct toxic effect on bone tissue, resulting in decreased bone formation and increased bone resorption. For those people who have excessive alcohol intake, alcohol calories decrease hunger and the need to take in adequate amounts of nutrients.

Osteoporosis also occurs in young adults who participate in excessive exercise or weight-loss dieting or in those who have eating disorders, such as anorexia nervosa or bulimia nervosa. Young females with these risk factors have a low body weight and absent menstruation, which contribute to the development of osteoporosis. Dancers, gymnasts, and other athletes may overtrain without sufficient caloric intake, which also results in severe weight loss. Young girls and women may have an obsession with being slim. Particular attention must be paid to bone health for these groups.

Incidence/Prevalence

Osteoporosis is a potential health problem for more than 44 million Americans. About 10 million people in the United States have the disease, and about 34 million people 50 years of age and older have osteopenia and are at risk for development of osteoporosis. Women remain the largest group affected by osteoporosis, although men, especially those older than 75 years, also have the disease. After the age of 50, men are at increased risk for osteoporosis and osteoporotic-related fractures (Voda, 2009b).

People of all ethnic and racial backgrounds are at some degree of risk, but white, thin women are likely to get primary osteoporosis at an earlier age (National Osteoporosis Foundation, 2010).

CULTURAL AWARENESS

Although there is some advantage of increased bone density in dark-skinned women, lifestyle and health beliefs about prevention may put all women at an equal risk for osteoporosis. Dietary preferences or the ability to afford high-nutrient food may influence the woman's rate of bone loss. For example, many blacks have lactose intolerance and cannot drink milk or eat other dairy-based foods. Milk and cheese are good sources of protein, a nutrient needed to bind calcium for use by the body.

Osteoporosis results in more than 1.5 million fractures each year. A woman who experiences a hip fracture has a four times greater risk for a second fracture. Fractures as a result of osteoporosis and falling can decrease a patient's mobility and quality of life. The mortality rate for older patients with hip fractures is very high, especially within the first 6 months, and the debilitating effects can be devastating.

Nursing home residents fall 11 times more often than their community-dwelling counterparts (Parikh et al., 2009). Yet, skilled nursing facilities (SNFs) do not routinely screen residents for osteoporosis. A national study by Gloth and Simonson (2008) reported the results of osteoporosis screening for more than 34,000 SNF residents in 26 states. Over 42% of residents were categorized as having a high risk for osteoporosis and associated fractures (see the Evidence-Based Practice box on p. 1122).

EVIDENCE-BASED PRACTICE

Is Osteoporosis Underdiagnosed in Residents Admitted to Skilled Nursing Facilities?

Gloth, F.M., 3rd, & Simonson, W. (2008). Osteoporosis is underdiagnosed in skilled nursing facilities: A large-scale heel BMD screening study. *Journal of the American Medical Directors Association*, 9(3), 190-193.

The purpose of this nationwide study in the United States was to investigate the belief that osteoporosis is underdiagnosed in the skilled nursing facility (SNF) setting. Local consultant pharmacists screened 34,486 SNF residents in 26 states using the peripheral dual-energy x-ray absorptiometry (DXA) scan to determine bone mineral density (BMD) of the heel. Residents ranged in age from younger than 59 years to older than 80 years. Of the total screened residents, 22.4% were categorized as low risk, 35.1% as moderate risk, and 42.5% as high risk for osteoporosis and related fractures. The researchers concluded that osteoporosis is grossly underdiagnosed and BMD screening should be a part of the resident's admission assessment.

Level of Evidence: 4

Although the sample was very large and the study answered the research question, no experimental or quasi-experimental design was used. However, it would be inappropriate to use these designs to answer the research question.

Commentary: Implications for Practice and Research

Nurses working with older adults in any setting need to be aware of the prevalence of osteoporosis among this population. They can be instrumental in developing screening programs that can identify the most at-risk older adults so they can be treated and monitored more carefully for fractures. Those at risk need to have health teaching about drug therapy and lifestyle changes that could slow or improve the disease process.

Health Promotion and Maintenance

Peak bone mass is achieved by about 30 years of age in most women. *Building strong bone as a young person may be the best defense against osteoporosis in later adulthood. Young women need to be aware of appropriate health and lifestyle practices that can prevent this potentially disabling disease.*

Nurses can play a vital role in patient education to prevent and manage osteoporosis. *Teaching should begin with young women because they begin to lose bone after 30 years of age.*

The focus of osteoporosis prevention is to decrease modifiable risk factors. For example, teach patients who do not include enough dietary calcium which foods should be included, such as dairy products and dark green, leafy vegetables. Teach them to read food labels for sources of calcium content. Explain the importance of sun exposure (but not so much as to get sunburned) and adequate vitamin D in the diet. In 2010, the Institute of Medicine published recommendations for healthy people younger than 71 years to take 600 international units of activated vitamin D each day; 800 to 1000 international units each day is recommended for people older than 71 years. The National Osteoporosis Foundation recommends higher doses for healthy people. Patients being treated for osteoporosis or osteomalacia (vitamin D deficiency) are prescribed much higher therapeutic doses.

Teach the need to limit the amount of carbonated beverages consumed each day. Remind patients who have sedentary lifestyles about the importance of exercise and what types of exercise builds bone tissue. Weight-bearing exercises, such as regularly scheduled walking, are preferred. Teach

people to avoid activities that cause jarring, such as horseback riding, to prevent potential vertebral compression fractures.

PATIENT-CENTERED COLLABORATIVE CARE**ASSESSMENT**

A complete health history with assessment of risk factors is important in the prevention, early detection, and treatment of osteoporosis. Patients who have risk factors for osteoporosis are at increased risk for fractures when falls occur. Include a fall risk assessment in the health history, especially for older adults. Assess for fall risk factors, including:

- Delirium
- Dementia
- Immobility
- Muscular weakness
- History of falls
- Visual or hearing deficits
- Current drugs

The Joint Commission's National Patient Safety Goals (NPSG) specify the need to reduce risk for harm to patients resulting from falls. *People with osteoporosis are at an increased risk for fracture if a fall occurs. The World Health Organization (WHO) Fracture Risk Algorithm (FRAX) is often used to determine the patient's risk for fractures associated with bone loss. Chapter 3 discusses falls in older adults in more detail.*

Physical Assessment/Clinical Manifestations

When performing a musculoskeletal assessment, inspect and palpate the vertebral column. The classic "dowager's hump," or kyphosis of the dorsal spine, is often present (Fig. 53-1). The patient may state that he or she has gotten shorter, perhaps as much as 2 to 3 inches (5 to 7.5 cm) within the previous 20 years. Take or delegate height and weight measurements, and compare with previous measurements if they are available.

The patient may have back pain, which often occurs after lifting, bending, or stooping. The pain may be sharp and acute in onset. Pain is worse with activity and is relieved by rest. Palpation of the vertebrae, particularly the lower thoracic and lumbar vertebrae, can increase the patient's discomfort. Therefore palpation should be gentle.

Back pain accompanied by tenderness and voluntary restriction of spinal movement suggests one or more compression vertebral fractures, the most common type of osteoporotic fracture. Movement restriction and spinal deformity may result in constipation, abdominal distention, reflux esophagitis, and respiratory compromise in severe cases. The most likely area for spinal fracture is between T8 and L3. This problem is discussed in more detail in Chapter 54.

Fractures are also common in the distal end of the radius (wrist) and the upper third of the femur (hip). Ask the patient to locate all areas that are painful, and observe for signs and symptoms of fractures, such as swelling and malalignment.

Psychosocial Assessment

Women associate osteoporosis with menopause, getting older, and becoming less independent. The disease can result in suffering, deformity, and disability that can affect the patient's well-being and life satisfaction. The quality of life

FIG. 53-1 A normal spine at age 40 years and osteoporotic changes at ages 60 and 70 years. These changes can cause a loss of as much as 6 inches in height and can result in the so-called *dowager's hump* (far right) in the upper thoracic vertebrae.

may be further impacted by pain, insomnia, depression, and **fallophobia** (fear of falling).

Assess the patient's concept of body image, especially if he or she is severely kyphotic. For example, the patient may have difficulty finding clothes that fit properly. Social interactions may be avoided because of a change in appearance or the physical limitations of being unable to sit in chairs in restaurants, movie theaters, and other places. Changes in sexuality may occur as a result of poor self-esteem or the discomfort caused by positioning during intercourse.

Because osteoporosis poses a risk for fractures, teach the patient to be extremely cautious about activities. As a result, the threat of fracture can create anxiety and fear and result in further limitation of social or physical activities. Assess for these feelings to assist in treatment decisions and health teaching. For example, the patient may not exercise as prescribed for fear that a fracture will occur.

Laboratory Assessment

There are no definitive laboratory tests that confirm a diagnosis of primary osteoporosis, although a number of *biochemical markers* can provide information about bone resorption and formation activity. These biochemical markers are sensitive to bone changes and can be used to monitor effectiveness of treatment for osteoporosis. *Bone-specific alkaline phosphatase (BSAP)* is found in the cell membrane of the osteoblast and indicates bone formation status. *Osteocalcin* is a protein substance in bone and increases during bone resorption activity. Pyridinium (PYD) cross-links are released into circulation during bone resorption. *N-telopeptide (NTX)* and *C-telopeptide (CTX)* are proteins released when bone is

broken down. Some laboratories require a 24-hour urine collection for testing, whereas others use a double-voided specimen. Some markers, like NTX and CTX, can also be measured in the blood using immunoassay techniques. Increased levels of any of these markers indicate a risk for osteoporosis. Increased levels are found in patients with osteoporosis, Paget's disease, and bone tumors (Pagana & Pagana, 2010).

A battery of tests can be performed to rule out secondary osteoporosis or other metabolic bone diseases, such as osteomalacia and Paget's disease. These include measurements of serum calcium, vitamin D, and phosphorus. Urinary calcium levels may also be assessed. Serum protein measurements and thyroid function tests are done to check for hyperthyroidism.

Imaging Assessment

Conventional x-rays of the spine and long bones show decreased bone density but only after a 25% to 40% bone loss has occurred. Fractures can also be seen on x-ray.

The most commonly used screening and diagnostic tool for measuring bone mineral density (BMD) is **dual x-ray absorptiometry (DXA)**. The spine and hip are most often assessed when central DXA (cDXA) scan is performed. Many physicians recommend that women in their 40s have a baseline screening DXA scan so that later bone changes can be detected and compared. DXA is a painless scan that emits less radiation than a chest x-ray. *It is the best tool currently available for a definite diagnosis of osteoporosis.* The patient stays dressed but is asked to remove any metallic objects such as belt buckles, coins, keys, or jewelry that might interfere with the test. The results are displayed on a computer graph, and

a T-score is calculated. No special follow-up care for the test is required. However, the patient needs to discuss the results with the physician for any decisions about possible preventive or management interventions.

A peripheral DXA (pDXA) scan assesses BMD of the heel, forearm, or finger. It is often used for large-scale screening purposes. For example, [Gloth and Simonson \(2008\)](#) reported a large-scale heel BMD study for screening over 34,000 skilled nursing facility residents. The pDXA is also commonly used for screening at community health fairs and women's health centers.

Quantitative computed tomography (QCT) can also measure bone density, using either a central or peripheral technique. This procedure analyzes trabecular and cortical bone separately and is especially sensitive to changes in the vertebral column. The test is more expensive than the DXA scan and exposes the patient to more radiation; however, it is a safe screening test ([National Osteoporosis Foundation, 2010](#)).

Peripheral quantitative ultrasound (pQUS) is an effective and low-cost peripheral screening tool that can detect osteoporosis and predict risk for hip fracture. The heel, tibia, and patella are most commonly tested. The procedure requires no special preparation, is quick, and has no radiation exposure or specific follow-up care ([Pagana & Pagana, 2010](#)). The National Osteoporosis Foundation recommends that men older than 70 years have the pQUS as a screening tool for the disease.

ANALYSIS

The most common problem for patients with osteoporosis or osteopenia is potential for fractures related to weak, porous bone tissue.

PLANNING AND IMPLEMENTATION

Planning: Expected Outcomes

The expected outcome is that the patient avoids fractures by preventing falls, managing risk factors, and adhering to preventive or treatment measures for bone loss.

Interventions

Because the patient is predisposed to fractures, nutritional therapy, exercise, lifestyle changes, and drug therapy are used to slow bone resorption and form new bone tissue. Patient education can help prevent osteoporosis or slow the progress. These measures help reduce the chance of fractures and their complications. The role of drug therapy has increased over the past decade and helps prevent fractures related to osteoporosis. Drug therapy should begin when the BMD T-score for the hip is below -2.0 with no other risk factors or when the T-score is below -1.5 with one or more risk factors or previous fracture.

Nutrition Therapy. The nutritional considerations for the treatment of a patient with a diagnosis of osteoporosis are the same as those for preventing the disease. Teach patients about the adequate amounts of protein, magnesium, vitamin K, and trace minerals that are needed for bone formation. Calcium and vitamin D intake should be increased. Teach patients to avoid excessive alcohol and caffeine consumption. For the patient who has sustained a fracture, adequate intake of protein, vitamin C, and iron is important to promote bone healing. People who are lactose intolerant can choose a variety

of soy and rice products that are fortified with calcium and vitamin D. In addition, calcium and vitamin D are added to many fruit juices, bread, and cereal products.

A variety of nutrients are needed to maintain bone health. *The promotion of a single nutrient will not prevent or treat osteoporosis.* Help the patient develop a nutritional plan that is most beneficial in maintaining bone health; the plan should emphasize fruits and vegetables, low-fat dairy and protein sources, increased fiber, and moderation in alcohol and caffeine ([National Osteoporosis Foundation, 2010](#)).

Lifestyle Changes. Exercise is important in the prevention and management of osteoporosis. It also plays a vital role in pain management, cardiovascular function, and an improved sense of well-being.

In collaboration with the health care provider, the physical therapist may prescribe exercises for strengthening the abdominal and back muscles for those at risk for vertebral fractures. These exercises improve posture and support for the spine. Abdominal muscle tightening, deep breathing, and pectoral stretching are stressed to increase lung capacity. Exercises for the extremity muscles include muscle-tightening, resistive, and range-of-motion (ROM) exercises. Encourage active ROM exercises, which improve joint mobility and increase muscle tone, as well as prescribed exercise activities. Swimming provides overall muscle exercise.

In addition to exercises for muscle strengthening, a general weight-bearing exercise program should be implemented. Teach patients that *walking for 30 minutes three to five times a week is the single most effective exercise for osteoporosis prevention.* Teach the patient that certain high-impact recreational activities, such as running, bowling, and horseback riding, may cause vertebral compression fractures and should be avoided.

In addition to nutrition and exercise, other lifestyle changes may be needed. Teach the patient to avoid tobacco in any form, especially cigarette smoking. The patient must be careful to prevent falls and other activities that can cause a fracture. Teach the patient about the importance of having a hazard-free environment, including avoiding scatter rugs, cluttered rooms, and wet floor areas.

Hospitals and long-term care facilities have risk management programs to assess for the risk for falls. For those patients at high risk, communicate this information to other members of the health care team, using colored armbands or other easy-to-recognize methods (National Patient Safety Goals). [Chapter 3](#) discusses fall prevention in health care agencies and at home in more detail.

NCLEX EXAMINATION CHALLENGE

Health Promotion and Maintenance

Which statement by the client regarding lifestyle changes to prevent osteoporosis indicates a need for further teaching by the nurse?

- A. "I need to eat more green, leafy vegetables and dairy products."
- B. "I will cut down the amount of wine I drink each night."
- C. "I plan to begin smoking cessation classes at the hospital."
- D. "I am going to want to work out 3 days a week at the gym."

Drug Therapy. The health care provider may prescribe calcium and vitamin D supplements, bisphosphonates, or estrogen agonist/antagonists (formerly called *selective*

estrogen receptor modulators), or a combination of several drugs to treat or prevent osteoporosis (Chart 53-2). Estrogen and combination hormone therapy are not used solely for osteoporosis prevention or management because they can increase other health risks such as breast cancer and myocardial infarction (Woman's Health Initiative, 2005).

Calcium and Vitamin D. Intake of *calcium* alone is not a treatment for osteoporosis, but calcium is an important part of a *prevention* program to promote bone health. Most people cannot or do not have enough calcium in their diet, and therefore calcium supplements are needed. Calcium carbonate, found in over-the-counter (OTC) drugs such as Os-Cal, is one of the most cost-effective supplement formulas. Calcium citrate, available OTC as Citracal, is often recommended for those who have gastric upset when taking a calcium supplement. Teach patients to take calcium supplements with food and 6 to 8 ounces of water, although Citracal can be taken anytime. It is best to divide the daily dose, with at least one third of the daily dose being taken in the evening. Teach women to start taking supplements in young adulthood to assist in maintaining peak bone mass. Instruct patients of any age to take calcium supplements that also contain activated vitamin D, such as Os-Cal Ultra.

Remind patients to take these supplements under the supervision of a health care provider. **Hypercalcemia** (excess serum calcium) can cause serious damage to the urinary system and other body systems. Teach patients to drink plenty of fluids to prevent urinary or renal calculi (stones). Chapter 13 describes the clinical manifestations of hypercalcemia.

Bisphosphonates. Bisphosphonates (BPs) slow bone resorption by binding with crystal elements in bone, especially spongy, trabecular bone tissue. They are the most common drugs used for osteoporosis, but some are also approved for Paget's disease and hypercalcemia related to cancer. Three FDA-approved BPs—alendronate (Fosamax), ibandronate (Boniva), and risedronate (Actonel)—are commonly used for the *prevention and treatment* of osteoporosis (National Osteoporosis Foundation, 2010). These drugs are available as oral preparations, with ibandronate (Boniva) also available as an IV preparation.

! NURSING SAFETY PRIORITY

Drug Alert

Do not confuse Fosamax with Flomax, a selective alpha-adrenergic blocker used for benign prostatic hyperplasia (BPH).

Oral BPs are commonly associated with a serious problem called **esophagitis** (inflammation of the esophagus). Esophageal ulcers have also been reported with the use of BPs, especially when the tablet is not completely swallowed.

! NURSING SAFETY PRIORITY

Drug Alert

Teach patients to take bisphosphonates (BPs) early in the morning with 8 ounces of water and wait 30 to 60 minutes in an upright position before eating. If chest discomfort occurs, a symptom of esophageal irritation, instruct patients to discontinue the drug and contact their health care provider. Patients with poor renal function, hypocalcemia, or gastroesophageal reflux disease (GERD) should not take BPs.

The most recent additions to the bisphosphonates are IV zoledronic acid (Reclast) and IV pamidronate (Aredia). For management of osteoporosis, Reclast is needed only once a year and Aredia is given every 3 to 6 months. Both drugs have been linked to a complication called jaw **osteonecrosis** (jaw bone death) in which infection and necrosis of the mandible or maxilla occur (Lee, 2009). The incidence of this serious problem is low but can be a complication of this infusion therapy.

! NURSING SAFETY PRIORITY

Drug Alert

Teach the patient to have an oral assessment and preventive dentistry before beginning any bisphosphonate therapy. Instruct the patient to inform any dentist who is planning invasive treatment, such as a tooth extraction or implant, that he or she is taking a BP (Cohen, 2010).

Estrogen Agonist/Antagonists. Formerly called the *selective estrogen receptor modulators* (SERMs), estrogen agonist/antagonists are a class of drugs designed to mimic estrogen in some parts of the body while blocking its effect elsewhere. Raloxifene (Evista) is currently the only approved drug in this class and is used for *prevention and treatment* of osteoporosis in postmenopausal women. Raloxifene increases bone mineral density (BMD), reduces bone resorption, and reduces the incidence of osteoporotic vertebral fractures. The drug should not be given to women who have a history of thromboembolism.

Other Agents. Parathyroid hormone is prepared as *teriparatide* under the brand name Forteo and is a bone-building agent approved for *treatment* of osteoporosis in postmenopausal women with high risk for fracture. Teach patients to self-administer Forteo as a daily subcutaneous injection. This drug stimulates new bone formation, thus increasing BMD. Reduced risk for fracture in the spine, hip, and wrist has been reported in women, and reduced risk for hip fracture has been reported in men. Patients may experience dizziness or leg cramping as side effects of Forteo (National Osteoporosis Foundation, 2010). Teach the patient to lie down if these problems occur and notify the health care provider as soon as possible.

Calcitonin is a thyroid hormone that inhibits osteoclastic activity, thus decreasing bone loss. It is used for the *treatment* of osteoporosis, Paget's disease, and hypercalcemia associated with cancer. The drug also has an analgesic effect after vertebral fracture, thereby promoting early recovery.

Calcitonin can be given subcutaneously or intranasally. The nasal route is preferred because it improves drug adherence, decreases side effects, and is convenient. However, the effect of calcitonin may decrease after use for 2 or more years. Patients may require a holiday from this treatment to maintain effectiveness. Teach the patient to alternate nares to prevent mucosal irritation, a common side effect. The drug must be refrigerated.

Community-Based Care

Patients with osteoporosis are usually managed at home. Osteoporosis disease-management programs managed by nurse practitioners have helped diagnose and treat the disease. Greene and Dell (2010) reported that over a 6-year period, a

CHART 53-2 COMMON EXAMPLES OF DRUG THERAPY

Osteoporosis

DRUG AND USUAL DOSAGE	PURPOSE OF DRUG	NURSING INTERVENTIONS	RATIONALES
Supplements			
Calcium (with vitamin D if needed) (e.g., Os-Cal, Citracal) 1-1.5 g in divided doses orally daily	Increases calcium intake (and vitamin D if needed)	Give a third of daily dose at bedtime. Push fluids. Assess for a history of urinary stones. Monitor serum calcium level. Monitor urinary calcium level (no more than 4 mg/kg in 24 hr). Observe for signs of hypercalcemia.	Calcium is most readily utilized by the body when the patient is fasting and immobile. Increased fluid intake aids in preventing the formation of calcium-based urinary stones. Calcium supplements are not given to patients who are susceptible to urinary stone formation. Hypercalcemia, or calcium excess, is a side effect of calcium supplementation. The kidneys attempt to excrete excess calcium. Hypercalcemia can result in urinary stones, cardiac dysrhythmias, and an increase or decrease in skeletal muscle tone.
Bisphosphonates			
Alendronate (Fosamax) or (Fosamax plus D) For Prevention: 5 mg orally daily or 35 mg orally weekly (available as tablet or liquid) For Treatment: 10 mg orally daily or 70 mg orally weekly with 2800-5600 international units of vitamin D	Prevents bone loss and increases bone density	Take on an empty stomach, first thing in the morning with a full glass of water. Take 30 minutes before food, drink, or other drugs. Remain upright, sitting or standing, for 30 minutes after administration. Take liquid (75 mL) and follow with 2 ounces of water.	Difficulty swallowing, esophagitis, esophageal ulcers, and gastric ulcers can result from alendronate therapy. Any of these should be reported to a health care provider as soon as possible.
Risedronate (Actonel) or (Actonel with Calcium) 5 mg orally daily, 35 mg orally every week, or 150 mg monthly	Same as for alendronate	Follow interventions for alendronate. Observe for CNS side/adverse effects, such as drowsiness, anxiety, agitation.	Same as for alendronate. Drug can also cause CNS effects that may not be tolerated.
Ibandronate (Boniva) 150 mg orally once every month or 3.375 mg IV every 3 months	Same as for alendronate	Take on the same day each month. Take on an empty stomach, first thing in the morning with a full glass of water. Take 60 minutes before food, drink, or other drugs. Remain upright for 1 hour after administration.	Same as for alendronate.
Zoledronic acid (Reclast, Zometa) For Prevention: 5 mg IV once every 2 years For Treatment: 5 mg IV once a year	Same as for other bisphosphonates	Infuse over 15-30 minutes. Make sure the patient has a dental examination before starting the drug. Do not give to patients who are sensitive to aspirin. Check serum creatinine before and after administering the drug.	The drug should not be infused too quickly to prevent rare complications such as atrial fibrillation. The drug can cause jaw or maxillary osteonecrosis, particularly if oral hygiene is poor. The patient may experience bronchoconstriction. The drug can cause renal insufficiency or kidney failure.
Estrogen Agonist/Antagonists*			
Raloxifene (Evista) 60 mg orally daily	Prevents bone loss and increases bone density	Teach patient signs and symptoms of VTE. Monitor liver function tests (LFTs) in collaboration with health care provider.	Raloxifene can cause increased risk for VTE, especially in the first 4 months of therapy. Raloxifene can cause increased LFT values or worsen hepatic disease (should not be given to patient who has liver disease).

CNS, Central nervous system; VTE, venous thromboembolism.

*Formerly Selective Estrogen Receptor Modulators (SERMs).

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

A 62-year-old patient visits the physician's office to receive her first treatment for osteoporosis. She has a recent history of a badly fractured ankle and osteopenia (for which she has been taking Actonel). Her mother and grandmother had osteoporosis and osteoarthritis. The patient does not smoke but enjoys an occasional glass of wine when she and her husband go out for dinner. She drinks only 1 or 2 cups of caffeinated beverages a day. Although she realizes the importance of regular exercise, she has no time to fit that into her schedule because she travels throughout the country for her job. As her office nurse, you will be monitoring her as she has her first dose of Reclast.

1. What risk factors does this patient have for osteopenia and osteoporosis?
2. What health teaching might this patient need? How can you help her plan time for increasing her physical activity level? What does current evidence show that supports your answer?
3. What actions will you take before starting her Reclast?
4. How fast will you administer the drug, and what method will you use?

large osteoporosis disease-management program resulted in a 263% increase in the number of DXA scans done each year, a 153% increase in the number of patients treated with drug therapy, and a 38.1% decrease in the expected hip fracture rate.

Some patients have fractures that may require hospitalization or medical management in an emergency department (ED) or urgent care setting. In any setting, assess for risk factors for osteoporosis and provide health teaching as appropriate.

The patient with osteoporosis who has one or more fractures may be discharged to the home setting. In some instances, though, the patient is transferred to a long-term care facility for rehabilitation or permanent residence when support systems are not available. Collaborate with case managers or discharge planners to assist in preparing patients and their families for placement in long-term care facilities. Chapter 54 discusses continuing care for patients who have fractures.

Refer patients to the National Osteoporosis Foundation (www.nof.org) in the United States to provide information to patients and health care professionals regarding the disease and its treatment. The Osteoporosis Society of Canada (www.osteoporosis.ca) has similar services. Large hospitals often have osteoporosis specialty clinics and support groups for patients with osteoporosis.

OSTEOMALACIA

Pathophysiology

Osteomalacia is loss of bone related to a vitamin D deficiency. It causes softening of the bone resulting from inadequate deposits of calcium and phosphorus in the bone matrix. Normal remodeling of the bone is disrupted, and calcification does not occur. Osteomalacia is the adult equivalent of **rickets**, or vitamin D deficiency, in children.

Vitamin D deficiency is the most important factor in development of osteomalacia. In its natural form, vitamin D is activated by the ultraviolet radiation of the sun and obtained from certain foods as a nutritional supplement. In combination with calcium and phosphorus, the vitamin is necessary for bone formation.

TABLE 53-2 DIFFERENTIAL FEATURES OF OSTEOPOROSIS AND OSTEOMALACIA

CHARACTERISTIC	OSTEOPOROSIS	OSTEOMALACIA
Definition	Decreased bone mass	Demineralized bone
Pathophysiology	Lack of calcium	Lack of vitamin D
Radiographic findings	Osteopenia, fractures	Pseudofractures, Looser's zones, fractures
Calcium level	Low or normal	Low or normal
Phosphate level	Normal	Low or normal
Parathyroid hormone	Normal	High or normal
Alkaline phosphatase	Normal	High

TABLE 53-3 CAUSES OF OSTEOMALACIA

Vitamin D Disturbance • Inadequate production • Lack of sunlight exposure • Dietary deficiency • Abnormal metabolism • Drug therapy • Phenytoin (Dilantin) • Fluoride • Barbiturates • Liver disease • Renal disease	• Inadequate absorption • Postgastrectomy • Malabsorption syndrome • Inflammatory bowel disease
	Kidney Disease • Chronic kidney disease • Acute tubular disorders • Acidosis • Hypophosphatemia
	Familial Metabolic Error • Hypophosphatemia

Osteomalacia is frequently confused with osteoporosis because of similar characteristics shared by the two disease processes. Table 53-2 compares and contrasts osteoporosis and osteomalacia.

In addition to primary disease related to lack of sunlight exposure or dietary intake, vitamin D deficiency caused by various health problems may result in osteomalacia (Table 53-3). Malabsorption of vitamin D from the small bowel is a common complication of partial or total gastrectomy and bypass or resection surgery of the small intestine. Disease of the small bowel, such as Crohn's disease, may cause decreased vitamin and mineral absorption.

Liver and pancreatic disorders disrupt vitamin D metabolism and decrease its production. Chronic kidney disease (CKD) interferes with the synthesis of calcitriol, the most active vitamin metabolite. Osteomalacia can also be caused by bone tumors (**oncogenic** or **tumor-induced osteomalacia**).

Conditions that contribute to phosphate depletion (hypophosphatemia) lead to osteomalacia because they stimulate movement from bone and prevent calcium uptake in the bone. Osteomalacia is also an adverse effect of certain drugs, particularly anticonvulsants, barbiturates, and fluoride. The exact mechanism for the drug effects is not known. Genetic deviations in vitamin D or phosphate metabolism may contribute to bone changes seen in osteomalacia.

Osteomalacia is not common in the United States and Western Europe. However, it is more common in less affluent nations and in countries where famine is common.

Newcomers from these countries may seek health care in the United States. Older adults are most at risk. This group may have inadequate exposure to sunlight or intake of vitamin D–fortified foods. People who adhere to very restrictive vegan diets without adequate supplement of vitamin D can also be at risk. Assess for the risk for osteomalacia in anyone who has poor nutritional intake related to homelessness, who severely abuses drugs or alcohol, or who is very poor.

Health Promotion and Maintenance

To prevent or help treat osteomalacia, teach patients to increase vitamin D through dietary intake, sun exposure, and drug supplements. Instruct the at-risk patient about foods high in vitamin D, such as milk and food that has had it added. Remind patients that cheese and yogurt rarely contain vitamin D although they are rich in calcium. Instruct them to read food labels for nutrient content. Remind patients, especially those who are homebound, about the importance of daily sun exposure (at least 5 minutes each day) for the most important source of vitamin D.

Some people are lactose intolerant or do not use dairy products because of their vegan diets. However, many products are available for people who avoid dairy products. Soy and rice milk, tofu, and soy products are substitutes, but they are expensive. Teach patients to choose those products that are fortified with vitamin D. Other foods rich in the vitamin are eggs, swordfish, chicken, and liver, as well as enriched cereals and bread products. The at-risk patient should also take vitamin D supplements as prescribed by his or her health care provider.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Collect important data for the patient with osteomalacia or suspected osteomalacia, including age, ability to be exposed to sunlight, and skin pigmentation. The older adult who has been homebound or chronically institutionalized is at the greatest risk. People who have dark skin and who may consume minimal protein are more at risk than light-skinned people with the same dietary habits. Dark-skinned people tend to avoid the sun and need protein for calcium binding. Take a thorough nutritional history to determine the intake of foods containing vitamin D and calcium. Coordinate the assessment with the dietitian.

Assessment includes any history of chronic disease processes of the GI tract including inflammatory bowel disease, gastric or intestinal bypass surgery, or any problem that interferes with absorption from the GI tract. A history of renal or liver dysfunction may lead to ineffective metabolism of vitamin D. Drugs such as phenytoin (Dilantin) or fluoride preparations may also interfere with metabolism of vitamin D.

Osteomalacia is easily confused with osteoporosis, and both disorders may occur at the same time (see Table 53-2). In the early stages of osteomalacia, the manifestations are nonspecific. Muscle weakness and bone pain may be misdiagnosed as arthritis or other connective tissue disorder. In some cases, proximal muscle weakness in the shoulder and pelvic girdle area is the only presenting symptom.

Muscle weakness in the lower extremities may cause a waddling and unsteady gait, which contributes to falls and subsequent fractures. Hypophosphatemia leads to an inadequate production of muscle cell adenosine triphosphate, thus resulting in a decrease in muscle cell energy. If hypocalcemia is present, muscle cramping may occur with weakness.

In collaboration with the physical therapist, assess muscle strength and observe the patient's gait. Document concerns about muscle cramps and bone pain. Skeletal discomfort is often vague and generalized. The spine, ribs, pelvis, and lower extremities are most often affected. The patient usually describes the pain as aggravated by activity and worse at night.

Palpate the affected bones for tenderness. Bone tenderness may occur when pressure is applied to the tibia or rib cage. Skeletal malalignment, like long-bone bowing or spinal deformity, may be similar to that seen in osteoporosis. In extreme cases, the pelvis narrows, so vaginal childbirth is difficult. If osteomalacia is untreated, vertebral, rib, and long-bone fractures may occur. The patient may be misdiagnosed as having bone cancer or osteoporosis.

X-rays of bone in patients with osteomalacia reveal a decrease in the cancellous bone and lack of osteoid sharpness. The classic diagnostic finding specific to the disease, however, is the presence of radiolucent bands (Looser's lines or zones). Looser's zones represent stress fractures that have not mineralized. They often appear symmetrically in the medial area of the femoral neck, ribs, and pelvis and may progress to complete fractures with minimal trauma. Bone biopsy of these areas may be needed for complete diagnosis. DXA scan may assist in diagnosis of osteomalacia.

INTERVENTIONS

The major treatment for osteomalacia is vitamin D in an active form, such as ergocalciferol. Studies indicate that large doses over a short period can correct low vitamin D status. For example, Przybelski et al. (2008) measured the serum vitamin D levels of 63 nursing home residents. Twenty-five residents had low serum levels and were given ergocalciferol 50,000 international units three times a week. After the treatment period, the mean total vitamin D serum concentration in the treated residents increased from 17.3 to 63.8 ng/mL. The researchers concluded that nursing home residents should be routinely screened to identify and treat those with low vitamin D levels to decrease the risk for fractures from osteomalacia and osteoporosis. Vitamin D is needed to adequately absorb and utilize calcium in the body.

Nurses play a vital role in educating other health care professionals about the need to screen patients for low vitamin D levels. For all at-risk patients, teach them about which high calcium and vitamin D foods to eat and the importance of adequate daily sunlight. Additional health teaching is discussed above in the Health Promotion and Maintenance section.

PAGET'S DISEASE OF THE BONE

Pathophysiology

Paget's disease, or **osteitis deformans**, is a chronic metabolic disorder in which bone is excessively broken down (osteoclastic activity) and re-formed (osteoblastic activity). The result is bone that is structurally disorganized, causing bones to be

weak with increased risk for bowing of long bones and fractures. Two types of Paget's disease can occur—familial and sporadic.

Three pathophysiologic phases of the disorder have been described: active, mixed, and inactive. In the first phase (the active phase), a rapid increase in osteoclasts (cells that break down bone) causes massive bone destruction and deformity. The osteoclasts of pagetic bone are large and multinuclear, unlike the osteoclasts of normal bone tissue.

In the mixed phase, the osteoblasts (bone-forming cells) react to compensate in forming new bone. The result is bone that is vascular, structurally weak, and deformed. Paget's disease occurs in one bone or in multiple sites. The most common areas of involvement are the vertebrae, femur, skull, clavicle, humerus, and pelvis.

When the osteoblastic activity exceeds the osteoclastic activity, the inactive phase occurs. The newly formed bone becomes sclerotic and very hard.

GENETIC/GENOMIC CONSIDERATIONS

Because Paget's disease is often present in identical twins, an autosomal dominant pattern has been suggested. The disease has been noted in up to 30% of people with a positive family history for Paget's disease. Several complex genetic factors have been identified in families with the disease, including mutations in the:

- *RANKL/RANK/OPG* system, which is needed for osteoclast development and activity (see p. 1121 in the Osteoporosis section)
- Valosin-containing gene of complement binding protein (*VCP*), an important inflammatory factor
- Sequestosome 1 (*SQSTM1*) or *p62*, an expressed adaptor protein that can bind to ubiquitin and the atypical protein kinase C (Najaf et al., 2009).

Teach patients the importance of genetics in familial Paget's disease, and refer them to the appropriate genetic counseling resource. Ask the patient if genetic testing is desired.

Paget's disease is second only to osteoporosis as one of the most common bone diseases in the United States, affecting about one million people. The disease is seen more frequently in people ages 50 years and older and in those of European heritage. The risk for developing Paget's disease increases as a person ages, particularly in those 80 years old and older. Men are affected twice as often as women (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2010).

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Physical Assessment/Clinical Manifestations

Most patients are asymptomatic, and the disease may be confined to one bone. It may be accidentally discovered during a routine laboratory or x-ray examination. In more severe disease, the manifestations are diverse and potentially fatal (Chart 53-3).

Ask the patient about a history of fracture and current bone pain. Bone pain, usually described as mild to moderate, may cause the patient to seek medical attention. The most common sites for pain are the hip and pelvis, but even the bones in the ear may be affected, causing hearing loss. The pain is usually described as aching, poorly defined, deep, and worsened by pressure. It is most noticeable at night or when

CHART 53-3 KEY FEATURES

Paget's Disease of the Bone

Musculoskeletal Manifestations

- Bone and joint pain (may be in a single bone) that is aching, poorly described, and aggravated by walking
- Low back and sciatic nerve pain
- Bowing of long bones
- Loss of normal spinal curvature
- Enlarged, thick skull
- Pathologic fractures
- Osteogenic sarcoma (bone cancer)

Skin Manifestations

- Flushed, warm skin

Other Manifestations

- Apathy, lethargy, fatigue
- Hyperparathyroidism
- Gout
- Urinary or renal stones
- Heart failure from fluid overload

the patient is resting. Patients may report redness and warmth at affected sites. These manifestations may be related to increased vascularity and blood flow.

The pain associated with the disorder may result from metabolic bone activity, secondary arthritis, impending fracture, or nerve impingement. Arthritis often occurs at the joints (cartilage) of the affected bones, resulting from bowing in the long bones of the leg. Some patients have joint replacements as a result of very painful weight-bearing joints. Nerve impingement is particularly common in the lumbosacral area of the vertebral column, presenting as back pain that radiates along one or both legs.

Observe posture, stance, and gait to identify gross bony deformities. Because of the enlargement of the vertebrae, loss of normal spinal curvature, and lower extremity malalignment, the patient may have decreased height. Assess for kyphosis or scoliosis of the spinal column. Note any long-bone bowing in the legs with subsequent varus (bow-leg) deformity. Long bones of the arms may also develop bowing. Flexion contracture in the hip joint is often present. Any of these deformities may be asymmetric. This weakened bone is at risk for fracture from even a minor injury. All of these problems interfere with the patient's need for independent mobility.

When performing a musculoskeletal assessment in a patient with Paget's disease, pay particular attention to the size and shape of the skull, which is typically soft, thick, and enlarged. Pressure from an enlarged temporal bone may lead to deafness and vertigo (dizziness). Basilar (in the occipital area) complications can compress any of the cranial nerves and result in neurologic problems. Assess the patient for changes in vision, swallowing, hearing, and speech. Platybasia, or basilar invagination, causes brainstem (vital sign center) damage that threatens life. In some cases, the bony enlargement of the skull blocks cerebrospinal fluid (CSF), resulting in hydrocephalus.

Pathologic fractures may be the presenting clinical manifestation of the disorder. The femur and the tibia are most often affected, and fracture of these bones can result from minimal trauma. The fracture line is usually perpendicular to the long axis of the bone, and healing is unpredictable because of abnormal metabolic activity within the bone.

Although rare, bones affected by Paget's disease may develop malignant changes. The most dreaded complication of Paget's disease is cancer, most commonly osteogenic sarcoma. Increased incidence of sarcoma occurs in men in the 70- to 80-year-old group. It affects the femur, humerus, and old fracture sites and has a grave prognosis because of early metastasis to the lung or extensive local invasion. When

severe bone pain is present in a patient with Paget's disease, bone cancer is suspected.

Assess the skin for its color and temperature. In people with Paget's disease, the skin is typically flushed and warm because of increased blood flow. In addition, assess the patient's energy level because apathy, lethargy, and fatigue are common.

Other less common manifestations of Paget's disease include hyperparathyroidism and gout. Secondary hyperparathyroidism leads to an increase in serum and urinary calcium levels. In severe cases, serum calcium excess results from prolonged immobilization. Calcium deposits occur in joint spaces or as stones in the urinary tract. **Hyperuricemia** (serum uric acid excess) and gout occur because the increased metabolic activity of bone creates an increase in nucleic acid catabolism. Therefore kidney stones are more common in people with Paget's disease.

In a few cases, increased blood flow causes the heart to work harder to increase cardiac output, resulting in heart failure if not treated. Cardiac complications tend to occur only when more than a third of the skeleton is involved.

Diagnostic Assessment

Increases in *serum alkaline phosphatase (ALP)* and urinary hydroxyproline levels are the primary laboratory findings indicating possible Paget's disease. Overactive osteoblasts cause an altered ALP level. ALP can be further evaluated by alkaline phosphatase isoenzymes. The isoenzyme testing can further break ALP into three fractions—liver, bone, and intestinal. Elevated bone isoenzymes can help in a more definitive diagnosis of Paget's disease. Serum isoenzyme levels of bone ALP are used to monitor effectiveness of treatment (Pagana & Pagana, 2010).

The 24-hour *urinary hydroxyproline* level reflects bone collagen turnover and indicates the degree of disease severity. The higher the hydroxyproline, the more severe is the disease.

The *calcium* levels in blood and urine may be low, normal, or elevated. The immobilized patient is more likely to have an increase in calcium levels as a result of calcium moving from bone into the blood.

Paget's disease often causes an elevated *uric acid* because nucleic acid from overactive bone metabolism increases. This finding may be misinterpreted as primary gout.

X-rays are also used to diagnose Paget's disease. They reveal characteristic changes including the presence of osteolytic lesions and enlarged bones with radiolucent, or punched-out, appearance. Decrease in joint space may be seen with arthritic changes in joints. Malalignment deformities, fractures, and secondary arthritic changes may be present.

Radionuclide bone scan may be most sensitive in detecting Paget's disease. A radiolabeled bisphosphonate is injected IV and shows pagetic bone in areas of high bone turnover activity. This test can determine the extent of Paget's disease in the skeleton. Computed tomography (CT) is useful in the detection of cancerous tumors, changes in the skull, and spinal cord or nerve compression. Magnetic resonance imaging (MRI) may also be used for the same purpose as the CT scan.

INTERVENTIONS

Nonsurgical or surgical management may be necessary to reduce pain and promote *mobility*. Nonsurgical interventions are used first.

Drug Therapy

The primary intervention for Paget's disease is drug therapy. Potent prescription drugs are used to treat Paget's disease. In addition, simple analgesics such as OTC NSAIDs can be used to control pain.

The purpose of *drug therapy* in Paget's disease is to relieve pain and to decrease bone resorption. Management of mild to moderate pain may include the use of aspirin or NSAIDs such as ibuprofen (Motrin, Apo-Ibuprofen ♣). When the calcium level is more than twice the normal value and the disease is widespread, the health care provider usually prescribes more potent drugs, such as selected bisphosphonates. Treatment with these agents for Paget's disease requires dosages and duration of therapy different from those for osteoporosis. **Chart 53-2** includes information about some of these commonly used drugs.

Oral bisphosphonates are a first-line treatment choice for Paget's disease when alkaline phosphatase levels are at least twice the normal serum level. Alendronate (Fosamax), risedronate (Actonel), etidronate (Didronel), and tiludronate (Skelid) are given in tablet form. When oral agents are not effective, pamidronate (Aredia) and zoledronic acid (Reclast, Zometa) are administered IV. Aredia is given once every 3 months, and Reclast is given once a year as a single IV dose. These drugs are usually highly effective. To reduce the risk for hypocalcemia, patients should receive 1500 mg of calcium daily in divided doses and 800 international units of vitamin D daily for at least 2 weeks after zoledronic acid infusion unless they are prone to kidney stones. **Chart 53-2** provides additional information about caring for patients receiving bisphosphonates.

Calcitonin is a hormone that seems to reduce bone resorption and, subsequently, relieve pain. The drug often causes a dramatic decrease in the alkaline phosphatase level in a few weeks. Calcitonin is approved for subcutaneous administration in treating Paget's disease because the nasal spray has shown to be ineffective. It binds to osteoclast receptors, therefore slowing bone breakdown. The drug may be used for those patients who do not tolerate bisphosphonates. Side effects of calcitonin include nausea, flushing, and skin rash. Skin testing may be done before administration of the first dose.

Other Interventions

In addition to administering drugs, implement physical measures to reduce pain and increase *mobility*. These measures may include application of heat and gentle massage. An exercise program may be started with the help of a physical therapist. Exercise may be difficult because of pain and danger of fracture. Non-impact exercise should be used, but the patient may benefit from strengthening and weight-bearing exercises. In collaboration with the physical therapist, teach the patient about ROM and gentle stretching. Additional interventions for pain relief, such as relaxation techniques, are discussed in **Chapter 5**.

Measures to promote bone health are also important and include a diet rich in calcium and vitamin D. Nutrition therapy for bone health is described on p. 1124 in the discussion of Interventions in the Osteoporosis section.

Provide the patient with information to contact the U.S. local chapter of The Paget Foundation (www.paget.org) and the Arthritis Foundation (www.arthritis.org). The Arthritis

Society in Canada (www.arthritis.ca) is also an excellent service. These resources provide information and support for the patient and family or significant others. Nutritional instruction should be similar to information given to the patient with osteoporosis.

NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client is starting on alendronate (Fosamax) for prevention of osteoporosis. What precaution will the nurse include in the client's health teaching about this drug?

- A. "Take with food or milk to prevent stomach upset."
- B. "Monitor the drug injection site for redness or itching."
- C. "Take the drug at night before you go to bed."
- D. "Do not lie down for at least 30 minutes after taking the drug."

OSTEOMYELITIS

Infection in bony tissue can be a severe and difficult-to-treat problem. Bone infection can result in chronic recurrence of infection, loss of function and mobility, amputation, and even death.

Pathophysiology

Bacteria, viruses, or fungi can cause infection in bone known as **osteomyelitis**. Invasion by one or more pathogenic microorganisms stimulates the inflammatory response in bone tissue. The inflammation produces an increased vascular leak and edema, often involving the surrounding soft tissues. Once inflammation is established, the vessels in the area become thrombosed and release exudate (pus) into bony tissue. Ischemia of bone tissue follows and results in necrotic bone. This area of necrotic bone separates from surrounding bone tissue, and **sequestrum** is formed. The presence of sequestrum prevents bone healing and causes superimposed infection, often in the form of bone abscess. As shown in Fig. 53-2, the cycle repeats itself as the new infection leads to further inflammation, vessel thromboses, and necrosis.

Osteomyelitis is categorized as **exogenous**, in which infectious organisms enter from outside the body as in an open fracture, or **endogenous**, in which organisms are carried by the bloodstream from other areas of infection in the body.

FIG. 53-2 Infection cycle of osteomyelitis.

Endogenous osteomyelitis may also be referred to as **hematogenous** osteomyelitis. A third category is **contiguous**, in which bone infection results from skin infection of adjacent tissues. Osteomyelitis can be further divided into two major types: acute osteomyelitis and chronic osteomyelitis.

Etiology

Each type of bone infection has its own causative factors. Pathogenic microbes favor bone that has a rich blood supply and a marrow cavity. **Acute hematogenous infection** results from bacteremia, underlying disease, or nonpenetrating trauma. Urinary tract infections, particularly in older men, tend to spread to the lower vertebrae. Long-term IV catheters (e.g., Hickman catheters) can be primary sources of infection. Patients undergoing long-term hemodialysis and IV drug abusers are also at risk for osteomyelitis. *Salmonella* infections of the GI tract may spread to bone. Patients with sickle cell disease and other hemoglobinopathies often have multiple episodes of salmonellosis, which can cause bone infection.

Poor dental hygiene and periodontal (gum) infection can be a causative factor in **contiguous** osteomyelitis in facial bones. Minimal nonpenetrating trauma can cause hemorrhages or small-vessel occlusions, leading to bone necrosis. Regardless of the source of infection, many infections are caused by *Staphylococcus aureus*. Treatment of infection may be complicated further by the presence of methicillin-resistant *Staphylococcus aureus* (MRSA) or other drug-resistant microorganism, which is very common in hospitalized and other institutionalized patients. One of the major desired outcomes in health care settings today is to reduce the number of MRSA infections from any source.

CONSIDERATIONS FOR OLDER ADULTS

Malignant external otitis media involving the base of the skull is sometimes seen in older adults with diabetes. The most common cause of contiguous spread in older adults, however, is found in those who have slow-healing foot ulcers. Multiple organisms tend to be responsible for the resulting osteomyelitis.

Penetrating trauma leads to acute osteomyelitis by direct inoculation. A soft-tissue infection may be present as well. Animal bites, puncture wounds, and bone surgery can result in bone infection. The most common offending organism is *Pseudomonas aeruginosa*, but other gram-negative bacteria may be found.

If bone infection is misdiagnosed or inadequately treated, **chronic osteomyelitis** may develop. Inadequate care management results when the treatment period is too short or when the treatment is delayed or inappropriate. About half of cases of chronic osteomyelitis are caused by gram-negative bacteria. Although bacteria are the most common causes of osteomyelitis, viruses and fungal organisms also may cause infection.

Incidence/Prevalence

Hematogenous osteomyelitis is the most common type of osteomyelitis. It occurs more often in children but is becoming increasingly common in adults, particularly older adults. Acute infection is more common in children. Chronic infection is more common in adults. Men have osteomyelitis more

often than women, related to a higher incidence of blunt or penetrating trauma. Conditions such as malnutrition, alcoholism, diabetes, kidney or liver disease, and immune-suppressing disorders increase the risk and complicate effective treatment. Bone tissues in the vertebrae and long bones are common sites of infection. The adult with a compromised blood supply is at greatest risk for chronic infection. Advanced age and concurrent disease may prolong the course of the infection for as long as a year or more.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

Bone pain, with or without other manifestations, is a common concern of patients with bone infection. The pain is described as a constant, localized, pulsating sensation that worsens with movement.

The patient with *acute* osteomyelitis has fever, usually with temperature greater than 101° F (38.3° C). *Older adults may not have an extreme temperature elevation because of lower core body temperature and compromised immune system that occur with normal aging.* The area around the infected bone swells and is tender when palpated. Erythema (redness) and heat may also be present. When vascular compromise is severe, patients may not feel discomfort because of nerve damage from lack of blood supply.

When vascular insufficiency is suspected, assess circulation in the distal extremities. Ulcerations may be present on the feet or hands, indicating inadequate healing ability as a result of poor circulation.

Fever, swelling, and erythema are less common in those with *chronic* osteomyelitis. Ulceration resulting in sinus tract formation, localized pain, and drainage is more characteristic of chronic infection (Chart 53-4).

The patient with acute osteomyelitis usually has an elevated white blood cell (leukocyte) count, which may be double the normal value. In chronic infection, normal values or slight elevations may be seen.

The erythrocyte sedimentation rate (ESR) may be normal early in the course of the disease but rises as the condition progresses. It may remain elevated for as long as 3 months after drug therapy is discontinued.

If bacteremia is present, a potentially life-threatening complication that could lead to septic shock, a blood culture identifies the offending organisms to determine which antibiotics should be used in treatment. Both aerobic and

anaerobic blood cultures should be collected before therapy is started.

Although bone changes cannot be detected early with standard x-rays, changes in blood flow can be seen early in the course of the disease by radionuclide scanning. A bone scan, using technetium or gallium, is extremely helpful in the diagnosis of osteomyelitis and identifies most cases. In some cases, MRI may be more sensitive than traditional bone scanning in the diagnosis of osteomyelitis.

INTERVENTIONS

The specific treatment protocol depends on the type and number of microbes present in the infected tissue. If other measures fail to resolve the infectious process, surgical management may be needed.

Nonsurgical Management

To reverse *acute* osteomyelitis, the health care provider starts antimicrobial (e.g., antibiotic) therapy as soon as possible. In the presence of copious wound drainage, Contact Precautions are used to prevent the spread of the offending organism to other patients and health care personnel. Teach patients, visitors, and staff members how to use these precautions. (See Chapter 25 for a discussion of Contact Precautions.)

IV antimicrobial therapy is usually prescribed for several weeks for acute osteomyelitis. More than one agent may be needed to combat multiple types of organisms. The hospital or home care nurse gives the drugs at specifically prescribed times so that therapeutic serum levels are achieved. Observe for the actions, side effects, and toxicity of these drugs. *Teach family members or other caregivers in the home setting how to administer antimicrobials if they are continued after hospital discharge or are used only at home.*

The optimal drug regimen for patients with chronic osteomyelitis is not well established. Prolonged therapy for more than 3 months may be needed to eliminate the infection. Because of the cost of lengthy hospital stays, patients are typically cared for in the home setting with long-term vascular access catheters, such as the peripherally inserted central catheter (PICC), for drug administration. After discontinuation of IV drugs, oral therapy may be needed for weeks or months. Patients and families must understand the complications of inadequate treatment or failure to follow up with health care providers. Teach them that drug therapy must be continued over a long period to be effective.

! NURSING SAFETY PRIORITY

Drug Alert

Even when symptoms of osteomyelitis appear to be improved, teach the patient and family that the full course of IV and oral antimicrobials must be completed to ensure that the infection is resolved.

CHART 53-4 KEY FEATURES

Acute and Chronic Osteomyelitis

Acute Osteomyelitis

- Fever; temperature usually above 101° F (38.3° C)
- Swelling around the affected area
- Erythema of the affected area
- Tenderness of the affected area
- Bone pain that is constant, localized, and pulsating; intensifies with movement

Chronic Osteomyelitis

- Ulceration of the skin
- Sinus tract formation
- Localized pain
- Drainage from the affected area

In addition to systemic drug therapy, the wound may be irrigated, either continuously or intermittently, with one or more antibiotic solutions. A medical technique in which beads made of bone cement are impregnated with an antibiotic and packed into the wound can provide direct contact of the antibiotic with the offending organism.

Drugs are also needed to control pain. Patients experience acute and chronic pain and must receive a regimen of drug

therapy for control. Chapter 5 describes pharmacologic and nonpharmacologic interventions for both acute and chronic pain.

If an open wound or ulcer is present in the hospital or long-term care setting, the patient's treatment usually includes Standard Precautions for limited infections in which the wound is not draining but is covered. This practice may vary according to health care agency policy. Contact Precautions are reserved for more severe infections, particularly when the purulent material cannot be adequately contained by a dressing. Cover the open area and use clean technique when dressings are changed to prevent further contamination. The previous clinical practice was to use strict aseptic technique, but most agencies are now using clean technique for contaminated ("dirty") wounds. Wounds may be managed through the window of a cast, which must remain dry during dressing or irrigation procedures. Teach patients and families how to continue clean dressing procedures at home.

A treatment to increase tissue perfusion for patients with chronic, unremitting osteomyelitis is the use of a hyperbaric chamber or portable device to administer hyperbaric oxygen (HBO) therapy. These devices are usually available in large tertiary care centers and may not be accessible to all patients who might benefit from them. With HBO therapy, the affected area is exposed to a high concentration of oxygen that diffuses into the tissues to promote healing. In conjunction with high-dose drug therapy and surgical débridement, HBO has proven very useful in treating a number of anaerobic infections. Other wound-management therapies are described in Chapter 27.

Surgical Management

Antimicrobial therapy alone may not meet the desired outcome of treatment. Surgical techniques may be used to minimize the disfigurement that can be a devastating result of severe osteomyelitis. Surgery is reserved for patients with chronic osteomyelitis.

Because bone cannot heal in the presence of necrotic tissue, a *sequestrectomy* may be performed to debride the necrotic bone and allow revascularization of tissue. The excision of dead and infected bone often results in a sizable cavity, or bone defect. The use of bone *grafts* to repair bone defects is also widely used.

When infected bone is extensively resected, reconstruction with *microvascular bone transfers* may be done. This procedure is reserved for larger skeletal defects. The most common donor sites are the patient's fibula and iliac crest. The bone graft may have an attached muscle or skin flap, if necessary. The steps of the procedure are similar to those of bone grafting in that débridement of dead or necrotic bone is done before bone transfer.

Nursing care of the patient after surgery is similar to that for any postoperative patient (see Chapter 18). However, the important difference is that neurovascular (NV) assessments must be done frequently because the patient experiences increased swelling after the surgical procedure. Elevate the affected extremity to increase venous return and thus control swelling. Assess and document the patient's NV status, including:

- Pain
- Movement
- Sensation

- Warmth
- Temperature
- Distal pulses
- Capillary refill (not as reliable as the above indicators)

! NURSING SAFETY PRIORITY

Critical Rescue

After surgery to treat osteomyelitis, frequently check for signs of neurovascular compromise, including pain that cannot be controlled, paresis or paralysis (weakness or inability to move), paresthesia (abnormal, tingling sensation), pallor, and pulselessness. If any of these findings occur, report them immediately to the surgeon.

If the bony defect is small, a *muscle flap* may be the only surgery required. Local muscle flaps are used in the treatment of chronic osteomyelitis when soft tissue does not fill the dead space, or cavity, resulting from bone débridement. The flap provides wound coverage and enhances blood flow to promote healing. A split-thickness skin graft is often applied several days after the muscle flap.

When the previously described surgical procedures are not appropriate or successful and as a last resort, the affected limb may need to be amputated. The physical and psychological care for a patient who has undergone an amputation is discussed in Chapter 54.

For all of the surgical procedures and their recovery phases, long-term antimicrobial treatment is necessary. The preoperative and postoperative nursing care is similar to that for repair of musculoskeletal trauma and is also discussed in Chapter 54.

BENIGN BONE TUMORS

Pathophysiology

Benign (noncancerous) bone tumors are often asymptomatic and may be discovered on routine x-ray examination or as the cause of pathologic fractures. The cause of benign bone tumors is not known. Tumors may arise from several types of tissue. The major classifications include **chondrogenic** tumors (from cartilage), **osteogenic** tumors (from bone), and **fibrogenic** tumors (from fibrous tissue and found most often in children). Although many specific benign tumors have been identified, only the common ones are described here.

The most common benign bone tumor is the *osteochondroma*. Although its onset is usually in childhood, the tumor grows until skeletal maturity and may not be diagnosed until adulthood. The tumor may be a single growth or multiple growths and can occur in any bone. The femur and the tibia are most often involved.

The *chondroma*, or *enchondroma*, is a lesion of mature hyaline cartilage affecting primarily the hands and the feet. The ribs, sternum, spine, and long bones may also be involved. Chondromas are slow growing and often cause pathologic fractures after minor injury. They are found in people of all ages, occur in both men and women, and can affect any bone.

The origin of the *giant cell tumor* remains uncertain. This lesion is aggressive and can be extensive and may involve surrounding soft tissue. Although classified as benign, giant cell tumors can metastasize (spread) to the lung. Unlike most other benign bone tumors, giant cell tumors affect women

older than 20 years. The peak incidence occurs in patients in their 30s.

PATIENT-CENTERED COLLABORATIVE CARE

Assess for pain, the most common manifestation of benign bone tumors. Pain can range from mild to moderate. It can be caused by direct tumor invasion into soft tissue, compressing peripheral nerves, or by a resulting pathologic fracture.

In addition to assessing the patient's pain, observe and palpate the suspected involved area. When the tumor affects the lower extremities or the small bones of the hands and feet, local swelling may be detected as the tumor enlarges. In some cases, muscle atrophy or muscle spasm may be present. Carefully palpate the bone and muscle to detect these changes and elicit tenderness.

Routine x-rays and tomography are used to find bone tumors. Tumors are characterized by sharp margins, intact cortices, and smooth, uniform periosteal bone.

CT is less useful except in complex anatomic areas, such as the spinal column and sacrum. The test is helpful in evaluating the extent of soft-tissue involvement. MRI may be especially helpful in viewing problems of the spinal column.

The health care provider uses drug therapy and surgery in combination when possible. Non-drug pain relief measures are also used. Depending on the patient's preference and tolerance, measures such as heat or cold may help relieve pain.

In addition to prescribing analgesics to reduce pain, the health care provider usually prescribes one or more NSAIDs to inhibit prostaglandin synthesis that increases pain and inflammation. Give these drugs after meals or with food to reduce GI side effects.

The most common surgical procedure used for benign bone tumors is removal. If the tumor is small, surgery may not be needed. When the tumor is very extensive, as in a giant cell tumor, it is removed with care to restore or maintain the function of the adjacent joint, most often the knee. In some cases, the knee is replaced with a prosthetic device and, less often, is fused (**arthrodesis**). Bone grafting may be needed. The collaborative care for patients undergoing these surgical procedures is discussed in [Chapter 20](#).

BONE CANCER

Cancerous bone tumors may be primary or secondary (those that originate in other tissues and metastasize to bone). *Primary tumors* occur most often in people between 10 and 30 years of age and make up a small percentage of bone cancers. As for other forms of cancer, the exact cause of bone cancer is unknown. *Metastatic lesions* most often occur in the older age-group and account for most bone cancers.

Previous radiation therapy in the anatomic area is a big risk factor. For example, bone cancer of the ribs in the path of radiation for breast cancer is fairly common.

Pathophysiology

Osteosarcoma, or osteogenic sarcoma, is the most common type of *primary* malignant bone tumor. More than 50% of cases occur in the distal femur, followed in decreasing order of occurrence by the proximal tibia and humerus.

The tumor is relatively large, causing acute pain and swelling. The involved area is usually warm because the blood flow

to the site increases. The center of the tumor is sclerotic from increased osteoblastic activity. The periphery is soft, extending through the bone cortex in the classic sunburst appearance associated with the neoplasm. An inward spread into the medullary canal is also common.

Osteosarcoma typically **metastasizes** (spreads) to the periphery of the lung within 2 years of treatment. Metastasis usually results in death.

Osteosarcoma occurs twice as often in males as in females between ages 10 and 30 years and in older patients with Paget's disease. Patients who have received radiation for other forms of cancer or who have benign lesions are also at high risk.

Although *Ewing's sarcoma* is not as common as other tumors, it is the most malignant. Like other primary tumors, it causes pain and swelling. In addition, systemic manifestations, particularly low-grade fever, leukocytosis, and anemia, characterize the lesions. The pelvis and the lower extremity are most often affected. Pelvic involvement is a poor prognostic sign. It often extends into soft tissue. Death results from metastasis to the lungs and other bones. Although the tumor can be seen in patients of any age, it usually occurs in children and young adults in their 20s. Men are affected more often than women.

In contrast to the patient with osteosarcoma, the patient with *chondrosarcoma* experiences dull pain and swelling for a long period. The tumor typically affects the pelvis and proximal femur near the diaphysis. Arising from cartilaginous tissue, it destroys bone and often calcifies. The patient with this type of tumor has a better prognosis than one with osteogenic sarcoma. Chondrosarcoma occurs in middle-aged and older people, with a slight predominance in men.

Arising from fibrous tissue, *fibrosarcomas* can be divided into subtypes, of which malignant fibrous histiocytoma (MFH) is the most malignant. Usually, the clinical presentation of MFH is gradual, without specific symptoms. Local tenderness, with or without a palpable mass, occurs in the long bones of the lower extremity. As with other bone cancers, the lesion can metastasize to the lungs. Although MFH affects people of all ages, it typically occurs in middle-aged men but is not common.

Primary tumors of the prostate, breast, kidney, thyroid, and lung are called *bone-seeking* cancers because they spread to the bone more often than other primary tumors. The vertebrae, pelvis, femur, and ribs are the bone sites commonly affected. Simply stated, primary tumor cells, or seeds, are carried to bone through the bloodstream. *Pathologic fractures caused by metastatic bone are a major concern in patient care management.* The most commonly affected areas for fracture are the acetabulum and the proximal femur.

Metastatic bone tumors greatly outnumber primary bone tumors. They affect primarily people older than 40 years. In patients with a history of cancer and local pain, bone metastasis is suspected.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

The data collected for the patient suspected of having a malignant bone tumor are similar to the data needed for the patient with a benign growth. In addition, ask whether the

patient has had previous radiation therapy for cancer and determine the status of the patient's general health.

The clinical manifestations seen in the patient with primary bone cancer or metastatic disease vary, depending on the specific type of lesion. Usually, the patient has a group of nonspecific concerns, including pain, local swelling, and a tender, palpable mass. Marked disability and impaired mobility may occur in those with advanced metastatic bone disease.

In a patient with Ewing's sarcoma, a low-grade fever may occur because of the systemic features of the neoplasm. For this reason, it is often confused with osteomyelitis. Fatigue and pallor resulting from anemia are also common.

In performing a musculoskeletal assessment, inspect the involved area and palpate the mass for size and tenderness. In collaboration with the physical and occupational therapists, assess the patient's ability to perform mobility tasks and ADLs.

Patients with malignant bone tumors may be young adults whose productive lives are just beginning. They need strong support systems to help cope with the diagnosis and its treatment. Family, significant others, and health care professionals are major components of the needed support. Determine what systems or resources are available.

Patients often experience a loss of control over their lives when a diagnosis of cancer is made. As a result, they become anxious and fearful about the outcome of their illness. Coping with the diagnosis becomes a challenge. As patients progress through the grieving process, there may be initial denial. Identify the anxiety level, and assess the stage or stages of the grieving process. Explore any maladaptive behavior, indicating ineffective coping mechanisms. [Chapter 24](#) further describes the psychosocial assessment for patients with cancer.

The patient with a malignant bone tumor typically shows elevated serum alkaline phosphatase (ALP) levels, indicating the body's attempt to form new bone by increasing osteoblastic activity. The patient with Ewing's sarcoma or metastatic bone cancer often has anemia. In addition, leukocytosis is common with Ewing's sarcoma. The progression of Ewing's sarcoma may be evaluated by elevated serum lactic dehydrogenase (LDH) levels.

In some patients with bone metastasis from the breast, kidney, or lung, the serum calcium level is elevated. Massive bone destruction stimulates release of the mineral into the bloodstream. In patients with Ewing's sarcoma and bone metastasis, the erythrocyte sedimentation rate (ESR) may be elevated because of secondary tissue inflammation.

As with benign bone tumors, routine x-rays and CT reveal malignant lesions. Although each tumor type has its own characteristic radiographic pattern, certain findings are common to all. Cancerous tumors typically show poor demonstration of bone margins, bone destruction, irregular periosteal new bone, and breakthrough of the cortical layer.

Metastatic lesions may increase or decrease bone density, depending on the amount of osteoblastic and osteoclastic activity. CT is helpful in determining the extent of soft-tissue damage. The patient may have an MRI for difficult-to-visualize areas such as the vertebrae.

In some cases, a needle bone biopsy may be performed, usually under fluoroscopy to guide the surgeon. Needle biopsy is an outpatient procedure with rare complications. After biopsy, the cancer is staged for size and degree of spread. One popular method is the TNM staging system, based on

tumor size and number (T), the presence of cancer cells in lymph nodes (N), and metastasis (spread) to distant sites (M).

Another staging method is to correlate the tumor grade (high or low), tumor site (intracompartmental or extracompartmental), and presence of metastatic disease (positive or negative). Staging guides the health care team in their decision regarding patient-centered collaborative care.

INTERVENTIONS

Because the pain is often due to direct primary tumor invasion, treatment is aimed at reducing the size of or removing the tumor. The expected outcome of treating metastatic bone tumors is palliative rather than curative. Palliative therapies may prevent further bone destruction and improve patient function. A combination of nonsurgical and surgical management is used. Members of the interdisciplinary health care team collaborate to plan the best approach for positive patient outcomes.

Nonsurgical Management

In addition to analgesics for local pain relief, chemotherapeutic agents and radiation therapy are often administered to shrink the tumor. In patients with spinal involvement, bracing and immobilization with cervical traction may reduce back pain. Interventional radiology techniques are used to decrease vertebral pain and treat compression fractures.

Drug Therapy. The physician may prescribe *chemotherapy* to be given alone or in combination with radiation or surgery. Certain proliferating tumors, such as Ewing's sarcoma, are sensitive to cytotoxic drugs. Others, such as chondrosarcomas, are often totally drug resistant. Chemotherapy seems to work best for small, metastatic tumors and may be administered before or after surgery. In most cases, the physician prescribes a combination of agents. At present, there is no universally accepted protocol of chemotherapeutic agents. The drugs selected are determined in part by the primary source of the cancer in metastatic disease. For example, when metastasis occurs from breast cancer, estrogen and progesterone blockers may be used. [Chapter 24](#) describes the general nursing care of patients who receive chemotherapy. Remember that all chemotherapeutic agents are categorized as high-alert medications ([Institute for Safe Medication Practices, 2008](#)).

Other drugs are given for specific metastatic cancers, depending on the location of the primary site. For example, biologic agents, such as cytokines, are given to stimulate the immune system to recognize and destroy cancer cells, especially in patients with renal cancer. Zoledronic acid (Zometa) and pamidronate (Aredia) are two IV bisphosphonates that are approved for bone metastasis from the breast, lung, and prostate. These drugs help protect bones and prevent fractures. Inform patients that osteonecrosis of the jaw may also occur, especially in those who have invasive dental procedures. Monitor associated laboratory tests, such as serum creatinine and electrolytes, because these drugs can be toxic to the kidneys.

Radiation Therapy. Radiation, either brachytherapy or external radiation, is used for selected types of malignant tumors. For patients with Ewing's sarcoma and early osteosarcoma, radiation may be the treatment of choice in reducing tumor size and thus pain.

For patients with metastatic disease, radiation is given primarily for palliation. The therapy is directed toward the painful sites to provide a more comfortable life span. One or

more treatments are given, depending on the extent of disease. With precise planning, radiation therapy can be used with minimal complications. The general nursing care for patients receiving radiation therapy is described in [Chapter 24](#).

Interventional Radiology. Interventional radiologists can perform several noninvasive procedures to help relieve pain in the patient with metastasis to the spinal column. Two types of *thermal ablation techniques*, *radiofrequency ablation (RFA)* and *cryoablation*, can be done under moderate sedation or general anesthesia. RFA kills the targeted tissue with heat using a small needle inserted into the tumor. Most patients have pain relief or control after this ambulatory care procedure. *Cryoablation* is similar to RFA, but the radiologist uses an extremely cold gas through a probe into the tumor. Although this procedure has been available for years, newer surgical equipment allows a small incision and the patient can return to usual daily activities in a day or two.

The radiologist may also perform a *vertebroplasty* if the patient with spinal metastasis has pathologic compression fractures. After making a small incision, bone cement is injected through a needle into the fractured area. The cement hardens within 15 minutes. Like thermal ablation, this procedure is done in an ambulatory care setting and the patient is placed under moderate sedation.

Surgical Management

Primary bone tumors are usually reduced or removed with surgery and often combined with radiation or chemotherapy.

Preoperative Care. In addition to the nature, progression, and extent of the tumor, the patient's age and general health state are considered. Chemotherapy may be administered preoperatively.

As for any patient preparing for cancer surgery, the patient with bone cancer needs psychological support from the nurse and other members of the health care team. Assess the level of the patient's and family's understanding about the surgery and related treatments. As an advocate, encourage the patient and family to discuss concerns and questions and provide information regarding hospital routines and procedures. Spiritual support is important to some patients. They may prefer to contact a member of the clergy or a spiritual leader or talk with a clergy member affiliated with the hospital. Assist in arranging for spiritual assistance if requested.

Anticipate postoperative needs as much as possible before the patient undergoes surgery. Remind the patient what to expect postoperatively and how to help ensure adequate recovery.

Operative Procedures. Wide or radical resection procedures are used for patients with bone sarcomas to salvage the affected limb. Wide excision is removal of the lesion surrounded by an intact cuff of normal tissue and leads to cure of low-grade tumors only. A radical resection includes removal of the lesion, the entire muscle, bone, and other tissues directly involved. It is the procedure used for high-grade tumors.

Large bone defects that result from tumor removal may require either:

- Total joint replacements with prosthetic implants, either whole or partial
- Custom metallic implants
- Allografts from the iliac crest, rib, or fibula

As an alternative to total replacement, an allograft may be implanted with internal fixation for those patients who do not have metastases. This is a common procedure for sarcomas of the proximal femur. Allograft procedures for the knee are also performed, particularly in young adults. Preoperative chemotherapy is given to enhance the likelihood of success. **Allografts** with adjacent tendons and ligaments are harvested from cadavers and can be frozen or freeze-dried for a prolonged period. The graft is fixed with a series of bolts, screws, or plates.

Although not commonly done, patients with metastatic disease intractable (not reversible) pain can be surgically treated with percutaneous **cordotomy** (cutting of the spinal nerve roots). **Cryosurgery** (cold application) may reduce pain and tumor size.

Postoperative Care. The surgical incision for a limb salvage procedure is often extensive. A pressure dressing with wound suction is typically maintained for several days. The patient who has undergone a limb salvage procedure has some degree of impaired physical mobility and a self-care deficit. The nature and extent of the alterations depend on the location and extent of the surgery.

! NURSING SAFETY PRIORITY

Action Alert

For patients who have allografts, observe for signs of hemorrhage, infection, or fracture. Report these changes to the surgeon immediately.

Muscle strengthening and range-of-motion (ROM) exercises begin immediately postoperatively and continue for at least a year. After upper extremity surgery, the patient can engage in active-assistive exercises by using the opposite hand to help achieve motions such as forward flexion and abduction of the shoulder. Continuous passive motion (CPM) using a CPM machine may be initiated as early as the first postoperative day for either upper extremity or lower extremity procedures.

After lower extremity surgery, the emphasis is on strengthening the quadriceps muscles by using passive and active motion when possible. Maintaining muscle tone is an important prerequisite to weight bearing, which progresses from toe touch or partial weight bearing to full weight bearing by 3 months postoperatively. Coordinate the patient's plan of care for ambulation and muscle strengthening with the physical therapist.

The patient who has had a bone graft may have a cast or other supportive device for several months. Weight bearing is prohibited until there is evidence that the graft is incorporated into the adjacent bone tissue.

During the recovery phase, the patient may also need assistance with ADLs, particularly if the surgery involves the upper extremity. Assist if needed, but at the same time encourage the patient to do as much as possible unaided. Some patients need assistive/adaptive devices for a short period while they are healing. Coordinate the patient's plan of care for promoting independence in ADLs with the occupational therapist.

Surrounding tissues, including nerves and blood vessels, may be removed during surgery. Vascular grafting is common,

but the lost nerve(s) is (are) usually not replaced. Assess the neurovascular status of the affected extremity and hand or foot every 1 to 2 hours immediately after surgery. Splinting or casting of the limb may also cause neurovascular (NV) compromise and needs to be checked for proper placement. Assess for NV compromise as described on p. 1133 under Surgical Management in the Osteomyelitis section.

Pelvic lesions, although not common, may also be surgically removed. Reconstruction generally entails bone fusion with muscle and nerve preservation. A hip spica cast or other device may be necessary until the graft has been incorporated. The patient may need a cane, crutches, or walker for ambulation.

The major complications of reconstructive surgery, such as a joint replacement, are superficial and deep wound infection, dislocation or loosening of the implants, and rapid neurovascular compromise. Report an increase in pain or temperature or a rapid deterioration in circulation to the surgeon promptly. Chapter 20 discusses postoperative care of patients having total joint replacements.

In addition to needing emotional support to cope with physical disabilities, the patient may need help coping with the surgery and its effects. Help identify available support systems as soon as possible.

As a result of most of the surgical procedures, the patient experiences an altered body image. Suggest ways to minimize cosmetic changes. For example, a lowered shoulder can be covered by a custom-made pad worn under clothing. The patient can cover lower extremity defects with pants.

The nurse's most important role is to be an active listener and to encourage the patient and family or significant others to verbalize their feelings. Counselors and members of the clergy or spiritual leaders may provide additional assistance in promoting acceptance of the diagnosis, treatment, or, possibly, impending death. Chapter 9 provides information about loss, death, and dying.

Regardless of the prognosis, a diagnosis of bone cancer is a major stressor that causes the patient and family or significant others to grieve. Help the patient and others cope with the loss and resolve the grief. Although patients are asked on admission to a health care agency if they want advance directives, they may have chosen not to have them. If a patient has terminal metastatic bone cancer, though, ask if he or she would like to complete advance directives, like a living will. If the patient already has written advance directives, be sure that a copy is on the medical record and has been given to the health care provider.

Advocate for the patient and the family to promote the physician-patient relationship. For instance, the patient may not completely understand the medical or surgical treatment plan but may hesitate to question the physician. The nurse's intervention can increase communication, which is essential in successful management of the patient with cancer.

Community-Based Care

After medical treatment for a primary malignant tumor, the patient is usually managed at home with follow-up care. The patient with metastatic disease may remain in the home or, when home support is not available, may be admitted to a long-term care facility for extended or hospice care. Coordinate the patient's discharge plan and continuity of care with

DECISION-MAKING CHALLENGE

Patient-Centered Care; Teamwork and Collaboration; Safety

A 75-year-old widow reports pain in her right rib cage area. She had a right simple mastectomy 8 years ago and was thought to be cancer-free until this time. A chest x-ray revealed bone metastasis in several ribs. On additional testing, the patient was found to also have multiple bone lesions in her right femur and pelvis. The patient is admitted to the cancer center for intensive treatment. Her only daughter is with her.

1. The patient states that she is very angry that her cancer has returned because she thought it was cured. She wonders if she should not have had a double mastectomy 8 years ago and perhaps the bone cancer could have been prevented. How will you respond to her feelings?
2. What treatment options does this patient have to manage her bone cancer? What is the purpose of treating the cancer at this time?
3. For what major complications is this patient most at risk and how will you plan to help prevent them? (Hint: See Chapter 24.)
4. With what health care team members will you collaborate and why?
5. What will you tell the daughter about her condition?
6. What are the major considerations for discharge planning?

the case manager and other health care team members, depending on the patient's needs.

Home Care Management

In collaboration with the occupational therapist, evaluate the patient's home environment for structural barriers that may hinder mobility. The patient may be discharged with a cast, walker, crutches, or a wheelchair.

Accessibility to eating and toileting facilities is essential to promote ADL independence. Because the patient with metastatic disease is susceptible to pathologic fractures, potential hazards that may contribute to falls or injury should be removed.

Teaching for Self-Management

For the patient receiving intermittent chemotherapy or radiation on an ambulatory basis, emphasize the importance of keeping appointments. Review the expected side and toxic effects of the drugs with the patient and family. Teach how to treat less serious side effects and when to contact the health care provider. If the drugs are administered at home via long-term IV catheter, explain and demonstrate the care involved with daily dressing changes and potential catheter complications. Chapter 15 describes the health teaching required for a patient receiving infusion therapy at home.

If the patient has undergone surgery, he or she has a wound and limited *mobility*. Teach the patient, family, and/or significant others how to care for the wound. Help the patient learn how to perform ADLs and mobility activities independently for self-management. Coordinate with the physical and occupational therapists to assist in ADL teaching, and provide or recommend assistive and adaptive devices, if necessary. The physical therapist also teaches the proper use of ambulatory aids, such as crutches, and exercises.

Pain management can be a major problem, particularly for the patient with metastatic bone disease. Discuss the various options for pain relief, including relaxation and music

therapy. Emphasize the importance of those techniques that worked during hospitalization.

The patient with bone cancer may fear that the malignancy will return. Acknowledge this fear, but reinforce confidence in the health care team and medical treatment chosen.

Mutually establish realistic outcomes regarding returning to work and participating in recreational activities. Encourage the patient to resume a functional lifestyle, but caution that it should be gradual. Certain activities, such as participating in sports, may be prohibited.

Help the patient with advanced metastatic bone disease prepare for death. The nurse and other support personnel assist the patient through the stages of death and dying. Identify resources that can help the patient write a will, visit with distant family members, or do whatever he or she thinks is needed for a peaceful death. In the later stages of the disease, hospice care may be an option (see Chapter 9). Nurses working in this area of care can be most helpful in managing end-of-life care.

Health Care Resources

In addition to family and significant others, cancer support groups are helpful to the patient with bone cancer. Some organizations, such as *I Can Cope*, provide information and emotional support. Others, such as *CanSurmount*, are geared more toward patient and family education. The American Cancer Society (www.cancer.org) and the Canadian Cancer Society (www.cancer.ca) can also provide education and resources for patients and families.

The hospital staff nurse, discharge planner, or case manager also ensures that follow-up care, including nursing care and physical or occupational therapy, is available in the home. The patient with terminal cancer may choose to become part of a hospice program.

DISORDERS OF THE HAND

Dupuytren's Contracture

Dupuytren's contracture, or deformity, is a slowly progressive thickening of the palmar fascia, resulting in flexion contracture of the fourth (ring) and fifth (little) fingers of the hand. The third or middle finger is occasionally affected. Although Dupuytren's contracture is a common problem, the cause is unknown. It usually occurs in older Euro-American men, tends to occur in families, and can be bilateral.

When function becomes impaired, surgical release is required. A partial or selective fasciectomy (cutting of fascia) is performed. After removal of the surgical dressing, a splint may be used. Nursing care is similar to that for the patient with carpal tunnel repair (see Chapter 54).

Ganglion

A **ganglion** is a round, benign cyst, often found on a wrist or foot joint or tendon. The synovium surrounding the tendon degenerates, allowing the tendon sheath tissue to become weak and distended. Ganglia are painless on palpation, but they can cause joint discomfort after prolonged joint use or minor trauma or strain. The lesion can rapidly disappear and then recur. Ganglia are most likely to develop in people between 15 and 50 years of age. With local or regional anesthesia in a physician's office or clinic, the fluid within the cyst can be aspirated through a small needle. A cortisone injection

FIG. 53-3 Appearance of hallux valgus with a bunion.

may follow. If the cyst is very large, it is removed using a small incision. Patients should avoid strenuous activity for 48 hours after surgery and report any signs of inflammation to their physician.

DISORDERS OF THE FOOT

Foot Deformities

The **hallux valgus** deformity is a common foot problem in which the great toe drifts laterally at the first metatarsophalangeal (MTP) joint (Fig. 53-3). The first metatarsal head becomes enlarged, resulting in a **bunion**. As the deviation worsens, the bony enlargement causes pain, particularly when shoes are worn. Women are affected more often than men. Hallux valgus often occurs as a result of poorly fitted shoes—in particular, those with narrow toes and high heels. Other causes include osteoarthritis, rheumatoid arthritis, and family history.

The surgical procedure, a simple **bunionectomy**, involves removal of the bony overgrowth and bursa and realignment. When other toe deformities accompany the condition or if the bony overgrowth is large, several **osteotomies**, or bone resections, may be performed. Fusions may also be performed. Screws or wires are often inserted to stabilize the bones in the great toe and first metatarsal during the healing process. If both feet are affected, one foot is usually treated at a time. Surgery usually is performed as a same-day procedure.

Most patients are allowed partial weight bearing while wearing an orthopedic boot or shoe. Walking is difficult because the feet bear body weight. The healing time after surgery may be more than 6 to 12 weeks because the feet receive less blood flow than other parts of the body because of their distance from the heart.

Often patients have hammertoes and hallux valgus deformities at the same time. As shown in Fig. 53-4, a **hammertoe**

FIG. 53-4 Hammertoe of the second metatarsophalangeal joint.

is the dorsiflexion of any MTP joint with plantar flexion of the proximal interphalangeal (PIP) joint next to it. The second toe is most often affected. As the deformity worsens, uncomfortable corns may develop on the dorsal side of the toe and calluses may appear on the plantar surface. Patients are uncomfortable when wearing shoes and walking.

Hammertoe may be treated by surgical correction of the deformity with **osteotomies** (bone resections) and the insertion of wires or screws for fixation. The postoperative course is similar to that for the patient with hallux valgus repair. The patient uses crutches until full weight bearing is allowed several weeks after surgery.

Morton's Neuroma

In the patient with **Morton's neuroma**, or plantar digital neuritis, a small tumor grows in a digital nerve of the foot. The patient usually describes the pain as an acute, burning sensation in the web space. The pain involves the entire surface of the third and fourth toes. Management involves surgical removal of the neuroma and application of a pressure dressing. Ambulation is usually permitted immediately after surgery.

Plantar Fasciitis

Plantar fasciitis is an inflammation of the plantar fascia, which is located in the area of the arch of the foot. It is often seen in middle-aged and older adults, as well as in athletes, especially runners. In ambulatory care settings, plantar fasciitis accounts for 10% of running injuries. Obesity is also a contributing factor.

Patients report severe pain in the arch of the foot, especially when getting out of bed. The pain is worsened with weight bearing. Although most patients have unilateral plantar fasciitis, the problem can affect both feet.

Most patients respond to conservative management, which includes rest, ice, stretching exercises, strapping of the foot to maintain the arch, shoes with good support, and orthotics. NSAIDs or steroids may be needed to control pain and

TABLE 53-4 TREATMENT OF COMMON FOOT PROBLEMS

DESCRIPTION/CAUSE	TREATMENT
Corn Induration and thickening of the skin caused by friction and pressure; painful conical mass	Surgical removal by podiatrist
Callus Flat, poorly defined mass on the sole over a bony prominence caused by pressure	Padding and lanolin creams; overall good skin hygiene
Ingrown Nail Nail sliver penetration of the skin, causing inflammation	Removal of sliver by podiatrist; warm soaks; antibiotic ointment
Hypertrophic Ungual Labium Chronic hypertrophy of nail lip caused by improper nail trimming; results from untreated ingrown nail	Surgical removal of necrotic nail and skin; treatment of secondary infection

inflammation. If conservative measures are unsuccessful, endoscopic surgery to remove the inflamed tissue may be required.

Teach the patient about the importance of adhering to the treatment plan and coordinating care with the physical therapist for instruction in exercise.

Other Problems of the Foot

Table 53-4 lists other common foot problems and how they are managed. Although patients are usually not hospitalized for these conditions, the nurse may recognize a foot disorder and alert the physician. Even small deformities or other foot deformities can be very annoying and painful for the patient and may hinder ambulation, as well as interfere with ADLs.

SCOLIOSIS

Pathophysiology

Scoliosis occurs when the vertebrae rotate and begin to compress. The spinal column begins to move into a lateral curve, most commonly in the right lateral thoracic area (see Fig. 52-3 in Chapter 52). As the degree of curvature increases, damage to the vertebral bodies results. The degree of the curvature increases during periods of growth, such as in adolescence. Curvature of greater than 50 degrees results in an unstable spine, and curvature of greater than 60 degrees in the thoracic spine results in compromise of cardiopulmonary function.

The exact cause of scoliosis is not well understood, yet it affects about 6 million people in the United States. The process may result from some problem in the balance mechanism located in the central nervous system. Females are affected more often than males, and onset is often in adolescence. School health nurses screen children for scoliosis during the middle school years. Information about caring for children with scoliosis is found in most pediatric nursing textbooks. Scoliosis that occurs in childhood or early adolescence may persist into adulthood.

Three types of scoliosis can be described: congenital, neuromuscular, and idiopathic; the most common curve pattern in adults is idiopathic scoliosis and the cause is unknown (Voda, 2009a). Congenital scoliosis occurs during embryonic development. Neuromuscular scoliosis can result from a neuromuscular condition in childhood or adulthood, such as cerebral palsy or spinal cord tumors. Untreated scoliosis can lead to back pain, deformity, and cardiopulmonary complications.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

A complete history of the patient with spinal deformity should include onset of problem, in adolescence or adulthood, and what treatments may have been used in the past. Patients who had surgery for scoliosis during adolescence are returning with progressive, debilitating back pain from degenerative disk disease below the level of vertebral fusion. A loss of lumbar curvature, or **lordosis**, described as “flat back” syndrome, may also be present. Complete a thorough pain assessment for patients reporting back pain.

Observe the patient from the front and back, while standing and during forward flexion from the hips. Physical examination usually reveals asymmetry of hip and shoulder height, prominence of the thoracic ribs and scapula on one side, and visible curve in the spinal column. Observation from the side may reveal kyphosis of the thoracic spine. Assess for leg length differences as well.

Methods of managing adult scoliosis differ from those used for children. The adult spinal column is less flexible and therefore less likely to respond to exercises, weight reduction, bracing, and casting for correction of the deformity. In the adult, the disorder is progressive and can result in an additional one degree of deviation each year.

INTERVENTIONS

Adults with less than 50 degrees of curvature of the spine may be treated conservatively with moist heat, pain medication, and exercise. Those with greater than 50 degrees of curvature may require surgical intervention to prevent shortness of breath and fatigue, osteoarthritis, and severe back pain.

The *surgical* reconstructive procedure consists of surgical fusion and insertion of instrumentation, including plates, screws, or rods to stabilize the spine. The surgeon performs spinal fusion by packing cancellous bone chips, usually from the iliac crest, between the affected vertebrae for support and stabilization. Both an anterior and a posterior approach may be needed. If so, the surgeon may perform both procedures during the same operative day or may stage them 7 to 10 days apart. The metal instrumentation supports the spine and immobilizes the fused area during healing.

! NURSING SAFETY PRIORITY

Action Alert

The priority for nursing care after spinal reconstructive surgery is to assess the patient's respiratory status and encourage deep breathing. Teach the patient how to use the incentive spirometer to prevent atelectasis.

Either an anterior or posterior surgical thoracic or abdominal approach may be used. For anterior thoracic surgery, a chest tube is in place for about 72 hours; for anterior abdominal surgery, the patient has a nasogastric tube for 24 hours. Other nursing care is similar to that for the patient undergoing a laminectomy or spinal fusion, including teaching the patient how to log roll, keeping the body in alignment (see Chapter 45).

Recognize that the patient having spinal reconstructive surgery will have a high level of anxiety and pain. Be sure to remind the patient how to use the IV patient-controlled analgesia. Assist him or her when sitting up, standing, and walking for the first time. Collaborate with the physical therapist to improve mobility and ambulation.

Teach patients and their families about home care, including how to care for the wound; body mechanics to prevent bending, twisting, and lifting; and how to adapt to achieve ADLs independently. Some patients may require home care nursing, physical therapy, or a home health aide for a short time after discharge (Voda, 2009a). Collaborate with the case manager to make the appropriate arrangements for continuity of care to meet the patient's needs.

For some patients, a return to work in about 3 to 6 weeks is realistic. Other surgical procedures may prevent the patient from performing these activities until 3 to 6 months postoperatively. Refer patients and their families to the National Scoliosis Foundation (www.scoliosis.org) for information and support services.

PROGRESSIVE MUSCULAR DYSTROPHIES

Many types of **muscular dystrophy (MD)** have been categorized as slowly progressive or rapidly progressive. The slowly progressive types are most commonly seen in adults. Most pediatric nursing books describe the care for patients with MD in detail. Four forms of MD are often seen in adults. Each type has its own distinct characteristics and causes, but all are progressive (Table 53-5).

The exact pathophysiologic mechanisms are unknown, but several causes are possible. These include:

GENETIC/GENOMIC CONSIDERATIONS

The major pathologic change that occurs in most types of MD is the production or faulty action of a muscle protein called **dystrophin**. The purpose of this protein is to maintain muscle integrity by sending signals to coordinate smooth, synchronous muscle fiber contraction. The coding of this protein is by a large gene that has many parts located on the X chromosome. Different mutations of the gene where dystrophin is located determine the degree of muscle weakness. Because this protein connects with other substances for final muscle action, genetic mutations of these other substances can make dystrophin fail to work properly.

The most common forms of MD are Duchenne MD (DMD) and Becker MD (BMD). Both are X-linked recessive disorders. Women who are *carriers* (able to pass on the gene without having the disorder) have a 50% chance of passing the MD gene to their daughters, who are then carriers, and to their sons, who then have the disease. These types of MD, then, affect only males. In DMD, most patients die very young and therefore do not have children. In BMD, the patient lives longer and may have children. None of these men's sons will have the disease, but their daughters will be carriers (Nussbaum et al., 2007). Refer carriers for genetic testing and counseling.

TABLE 53-5 DIFFERENTIAL FEATURES OF COMMON MUSCULAR DYSTROPHIES SEEN IN ADULTS

ONSET	GENETIC LINK	CLINICAL MANIFESTATIONS	PROGRESSION
Becker (Benign X-Linked) Dystrophy			
5-25 yr	Sex-linked recessive; expression in males	Wasting of pelvic and shoulder muscles; normal cardiac and mental function	Gradual progression; inability to walk 25 yr after onset; usually normal life span
Limb-Girdle Dystrophy			
Usually 20s or 30s	Usually autosomal dominant; expression in either gender	Upper extremity and neck muscles and lower extremity and hip muscle weakness	Extremely variable; severe disability within 10-20 yr after onset; life span shortened by 10-20 yr
Facioscapulohumeral (Landouzy-Dejerine) Dystrophy			
Usually in 20s	Autosomal dominant; expression in either gender	Facial and shoulder girdle muscle involvement	Usually benign; normal life span
Myotonic (Steinert) Dystrophy			
Birth to 40s	Autosomal dominant; expression in either gender	Muscle atrophy with multiple organ involvement (e.g., heart, lungs, smooth muscle, and endocrine system)	Usually gradual if onset in adulthood

- Poor blood flow to muscle resulting in reduced tissue oxygenation
- Disturbance in nerve-muscle interaction
- Loss of cell membrane integrity as a result of increased enzyme activity

Regardless of the type of MD, the primary problem is progressive muscle weakness. The major cause of death is respiratory failure caused by profound respiratory muscle weakness. Cardiac failure also occurs because dystrophin activity is needed for cardiac muscle contraction and maintenance.

Diagnosis of MD is often difficult because the clinical manifestations are similar to those of other muscular disorders. Muscle biopsy often confirms the diagnosis. Muscle weakness and trophic changes are characteristic of all types of MD. Serum muscle enzyme values, such as aldolase and creatine kinase, may be elevated, and electromyographic (EMG) findings are often abnormal.

Collaborative care of the patient with MD is supportive and involves the entire health care team. Physical and occupational therapy help the patient maintain as much function, *mobility*, and independence as possible. Refer the patient and family to the local chapter of the Muscular Dystrophy

Association (www.mda.org) for support services and information.

Major organ or body system involvement is medically managed, but the life span is often shortened from these manifestations of the disease. With the exception of steroids, no drug has been found to slow the progression of the disorder, although immunosuppressive agents, anabolic steroids, and growth factors have been tried.

An experimental treatment, myoblast transfer therapy (MTT), has been supported by the Food and Drug Administration (FDA). MTT involves injections of healthy muscle cells (myoblasts) taken from a donor and multiplied in a laboratory. The cells are then given to the patient with MD, where they theoretically fuse with each other and the recipient's unhealthy muscle cells. Gene therapy may also be an option for curing MD in the future.

Nursing interventions focus on making the patient as comfortable as possible and reinforcing techniques and exercises taught in the physical therapy program. The nurse's role in caring for a patient with cardiac or other organ involvement is the same as for any patient with dysfunction of these systems.

NURSING CONCEPT REVIEW

What might you NOTICE if the patient has impaired mobility as a result of chronic musculoskeletal disorders?

- Spinal deformity (e.g., kyphosis, lateral deviation)
- Bone malalignment (e.g., leg bowing)
- Muscle weakness
- Bone swelling or deformity
- Fracture
- Joint inflammation
- Flushed skin (Paget's disease)
- Fever (bone infection)
- Report of pain
- Report of weight loss

What should you INTERPRET and how should you RESPOND to a patient with impaired mobility as a result of chronic musculoskeletal disorders?

Perform and interpret focused physical assessment findings, including:

- Ability to ambulate (with or without assistive device)
- ADLs ability
- Body weight
- Pain intensity and quality
- Neurovascular assessment findings
- Ability to cope with decreased mobility

NURSING CONCEPT REVIEW—cont'd

Respond:

- Provide pain control interventions, including drugs and nonpharmacologic measures.
- Collaborate with members of the health care team, including PT, OT, dietitian, as needed.
- Teach about drugs that may be needed for long-term use, including side and toxic effects.
- Explain about the need for adequate calcium and vitamin D for healthy bones and bone healing.
- Assist with ADLs and ambulation as needed, but encourage independence when possible.
- Implement measures to prevent patient falls in the inpatient and home setting.
- Encourage the patient to discuss feelings related to disorders causing impaired mobility.
- Refer patients to appropriate community resources, such as the National Osteoporosis Foundation and Paget Disease Foundation.

On what should you REFLECT?

- Monitor the patient's response to pain control interventions.
- Prevent and monitor the patient for falls.
- Evaluate the patient's knowledge of nutrition and drug therapy.
- Evaluate the patient's coping ability related to disease diagnosis and treatment.
- Think about what else you might do to promote mobility.
- Decide whether you need to provide alternative interventions or additional health teaching.

GET READY FOR THE NCLEX® EXAMINATION!

KEY POINTS

Review these Key Points for each NCLEX Examination Client Needs Category.

Safe and Effective Care Environment

- Coordinate with health care team members when assessing patients with osteoporosis for risk for falls.
- In coordination with the physical and occupational therapists, educate the patient and family on home safety when the patient has a metabolic bone disease, such as osteoporosis.
- Refer to The Joint Commission for information about National Patient Safety Goals related to fall injury prevention.

Health Promotion and Maintenance

- Teach patients at risk for osteoporosis to minimize risk factors, such as stopping smoking, decreasing alcohol intake, exercising regularly, and increasing dietary calcium.
- Remind patients at risk for osteoporosis to have regular screening tests, such as the DXA scan.
- Instruct older adults to have at least 5 minutes of sun per day and to eat vitamin D–fortified foods to prevent osteomalacia.
- Refer patients with genetic-associated diseases for genetic testing and counseling.
- Assess the genetic risk for patients who have parents with muscular dystrophy.
- Refer patients with musculoskeletal problems to appropriate community resources, such as the Paget Disease Foundation and the National Osteoporosis Foundation.

Psychosocial Integrity

- Assist patients with osteoporosis to overcome fear of falling, or fallophobia, which prevents them from

socializing or going outside their homes. Collaborate with the physical therapist to determine whether ambulatory devices such as canes are indicated.

Physiological Integrity

- Remind patients taking bisphosphonates (BPs) to take them early in the morning, at least 30 to 60 minutes before breakfast, with a full glass of water and to remain sitting upright during that time to prevent esophagitis, a common complication of BP therapy.
- Most patients are unaware that they have osteoporosis until they experience a fracture, the most common complication of the disease.
- Osteomalacia, the result of a deficiency in vitamin D, can be caused by the factors listed in [Table 53-3](#).
- Remember that severe chronic pain is a priority for patients with metastatic bone disease.
- Use appropriate infection control practices when caring for patients with an open wound associated with osteomyelitis.
- For patients who have surgery for bone cancer, report postoperative manifestations of infection, dislocation, or neurovascular compromise to the surgeon promptly.
- Assess for key features of Paget's disease as summarized in [Chart 53-3](#).
- Remember that bone tumors can be benign or malignant.
- Be aware that even minor hand and foot problems can be very painful. Common foot problems are described in [Table 53-4](#).
- In collaboration with the health care team, provide supportive care for the patient with muscular dystrophy.
- Recognize that most major types of muscular dystrophy are genetic and manifest usually in childhood. Care is supportive.

Care of Patients with Musculoskeletal Trauma

Key Points
Review Questions for the NCLEX® Examination

LEARNING OUTCOMES

Safe and Effective Care Environment

1. Explain the importance of collaborating with the health care team when providing care for patients with fractures and amputations.
2. Apply principles of infection control when caring for a patient with a compound fracture.

Health Promotion and Maintenance

3. Identify community resources about amputations for patients and their families.
4. Recognize the importance of teaching the public about ways to prevent fractures and other musculoskeletal injuries.
5. Plan discharge teaching for patients with fractures or amputations.
6. Plan care that meets the special needs of older adults with hip fractures, including interventions to increase mobility.

Psychosocial Integrity

7. Describe how to assess the patient's and family's reaction to changes in body image resulting from amputation.
8. Explain how to assist patients in coping with loss of a body part.

Physiological Integrity

9. Compare and contrast common types of fractures.
10. Describe the usual healing process for bone.

11. Assess patients with musculoskeletal trauma to prioritize interventions for their care.
12. Explain the typical clinical manifestations that are seen in patients with fractures.
13. Delineate nursing care needed to maintain casts for patients with fractures.
14. Delineate nursing care needed to maintain traction and external fixation for patients with fractures.
15. Plan pain management for patients with musculoskeletal trauma.
16. Identify the risk for complications from fractures, and take measures to help prevent them.
17. Describe how to perform focused musculoskeletal and neurovascular assessment for patients with musculoskeletal trauma.
18. Develop a postoperative plan of care, including health teaching, for a patient after fracture repair.
19. Describe emergency care for people who have a traumatic amputation.
20. Plan postoperative care, including health teaching, after an elective amputation.
21. Identify common causes of amputations.
22. Identify appropriate complementary and alternative therapies for patients with phantom limb pain.
23. Describe the patient-centered collaborative care needed to manage complex regional pain syndrome.
24. Plan care for patients with common types of sports-related injuries.

Musculoskeletal trauma accounts for about two thirds of all injuries and is one of the primary causes of disability in the United States. It ranges from simple muscle strain to multiple bone fractures with severe soft-tissue damage.

Fractures and other musculoskeletal trauma impair a patient's *mobility* in varying degrees, depending on the severity and extent of the injury. These injuries also affect *sensation* because of pressure on nerve endings from edema. In some cases, peripheral nerves are directly damaged as a result of musculoskeletal injury.

FRACTURES

Pathophysiology

A **fracture** is a break or disruption in the continuity of a bone that often affects *mobility and sensation*. It can occur anywhere in the body and at any age. All fractures have the same basic pathophysiologic mechanism and require similar patient-centered collaborative care, regardless of fracture type or location.

Classification of Fractures

A fracture is classified by the extent of the break:

- **Complete fracture.** The break is across the entire width of the bone in such a way that the bone is divided into two distinct sections.
- **Incomplete fracture.** The fracture does not divide the bone into two portions because the break is through only part of the bone.

A fracture is described by the extent of associated soft-tissue damage as **open** (or **compound**) or **closed** (or **simple**). The skin surface over the broken bone is disrupted in a **compound** fracture, which causes an external wound. These fractures are often graded to define the extent of tissue damage. A **simple** fracture does not extend through the skin and therefore has no visible wound.

Fig. 54-1 shows common types of fractures. In addition to being identified by type, fractures are described by their cause. A **pathologic (spontaneous) fracture** occurs after minimal trauma to a bone that has been weakened by disease. For example, a patient with bone cancer or osteoporosis can

FIG. 54-1 Common types of fractures.

easily have a pathologic fracture. A **fatigue (stress) fracture** results from excessive strain and stress on the bone. This problem is commonly seen in recreational and professional athletes. **Compression fractures** are produced by a loading force applied to the long axis of cancellous bone. They commonly occur in the vertebrae of older patients with osteoporosis and are extremely painful.

Stages of Bone Healing

When a bone is fractured, the body immediately begins the healing process to repair the injury and restore the body's equilibrium. Fractures heal in five stages that are a continuous process and not single stages. In stage one, within 24 to 72 hours after the injury, a hematoma forms at the site of the fracture because bone is extremely vascular. Stage two occurs in 3 days to 2 weeks when granulation tissue begins to invade the hematoma. This then prompts the formation of fibrocartilage, providing the foundation for bone healing. Stage three of bone healing occurs as a result of vascular and cellular proliferation. The fracture site is surrounded by new vascular tissue known as a **callus** (within 3 to 6 weeks). **Callus** formation is the beginning of a nonbony union. As healing continues in stage four, the callus is gradually resorbed and transformed into bone. This stage usually takes 3 to 8 weeks. During the fifth and final stage of healing, consolidation and remodeling of bone continue to meet mechanical demands. This process may start as early as 4 to 6 weeks after fracture and can continue for up to 1 year, depending on the severity of the injury and the age and health of the patient. Fig. 54-2 summarizes the stages of bone healing.

In young, healthy adult bone, healing takes about 4 to 6 weeks. In the older person who has reduced bone mass, healing time is lengthened. Complete healing often takes 3 to 6 months or longer in people who are older than 70 years. Other factors also affect healing. Examples include the severity of the trauma, the type of bone injured, how the fracture is managed, infections at the fracture site, and ischemic or avascular necrosis (AVN).

CONSIDERATIONS FOR OLDER ADULTS

Bone healing is often affected by the aging process. Bone formation and strength rely on adequate nutrition. Calcium, phosphorus, vitamin D, and protein are necessary for the production of new bone (see Chapter 53). For women, the loss of estrogen after menopause decreases the body's ability to form new bone tissue. Chronic diseases can also affect the rate at which bone heals. For instance, peripheral vascular diseases, such as arteriosclerosis, reduce arterial circulation to bone. Thus the bone receives less oxygen and fewer nutrients, both of which are needed for repair.

Complications of Fractures

Regardless of the type or location of the fracture, several limb- and life-threatening acute and chronic complications can result from the injury. Clinical manifestations of beginning complications must be treated early to prevent serious consequences. In some cases, careful monitoring and assessment can prevent these complications:

- Acute compartment syndrome
- Crush syndrome
- Hypovolemic shock
- Fat embolism syndrome
- Venous thromboembolism
- Infection
- Chronic complications, such as ischemic necrosis and delayed union

Acute Compartment Syndrome. Compartments are areas in the body in which muscles, blood vessels, and nerves are contained within fascia. Most compartments are located in the extremities. **Fascia** is an inelastic tissue that surrounds groups of muscles, blood vessels, and nerves in the body. **Acute compartment syndrome (ACS)** is a serious condition in which increased pressure within one or more compartments reduces circulation to the area. The most common sites for this problem in patients with musculoskeletal trauma are the compartments in the lower leg and forearm.

FIG. 54-2 The stages of bone healing.

CHART 54-1 KEY FEATURES

Compartment Syndrome

PHYSIOLOGIC CHANGE	CLINICAL FINDINGS
Increased compartment pressure	No change
Increased capillary permeability	Edema
Release of histamine	Increased edema
Increased blood flow to area	Pulses present Pink tissue
Pressure on nerve endings	Pain
Increased tissue pressure	Referred pain to compartment
Decreased tissue perfusion	Increased edema
Decreased oxygen to tissues	Pallor
Increased production of lactic acid	Unequal pulses Flexed posture
Anaerobic metabolism	Cyanosis
Vasodilation	Increased edema
Increased blood flow	Tense muscle swelling
Increased tissue pressure	Tingling Numbness
Increased edema	Paresthesia
Muscle ischemia	Severe pain unrelieved by drugs
Tissue necrosis	Paresis/paralysis

The pathophysiologic changes of increased compartment pressure are sometimes referred to as the *ischemia-edema cycle*. Capillaries within the muscle dilate, which raises capillary pressure. Capillaries then become more permeable because of the release of histamine by the ischemic muscle tissue. As a result, plasma proteins leak into the interstitial fluid space and edema occurs. Edema increases pressure on nerve endings and causes pain. Blood flow to the area is reduced, and further ischemia results. Sensory deficits or paresthesia generally appears before changes in vascular or motor signs. The color of the tissue pales, and pulses begin to weaken but rarely disappear. The affected area is usually palpably tense, and pain occurs with passive motion of the extremity. If the condition is not treated, cyanosis, tingling, numbness, paresis, necrosis, and severe pain can occur. [Chart 54-1](#) summarizes the sequence of pathophysiologic events in compartment syndrome and the associated clinical assessment findings.

The pressure to the compartment can be from an external or internal source. Tight, bulky dressings and casts are examples of *external* pressure. Blood or fluid accumulation in the compartment is a common source of *internal* pressure. The injury or trauma causing the problem is above the compartment involved, which decreases blood flow to the more distal area of injury. ACS is not limited to patients with musculoskeletal problems. It can also occur in those with severe burns, extensive insect bites or snakebites, or massive infiltration of IV fluids. In these situations, edema increases internal pressure in one or more compartments.

Problems resulting from compartment syndrome include infection, persistent motor weakness in the affected extremity, contracture, and myoglobinuric renal failure. In extreme cases, amputation becomes necessary.

Infection from necrosis may become severe enough that amputation of the limb is needed. *Motor weakness* from

injured nerves is not reversible, and the patient may require an orthotic device for assistance in mobility. Volkmann's *contractures* of the forearm, which can begin within 12 hours of the pressure increase, result from shortening of the ischemic muscle and from nerve involvement.

Myoglobinuric renal failure from muscle breakdown is a potentially fatal complication of compartment syndrome. It occurs when large or multiple compartments are involved. Injured muscle tissues release myoglobin (muscle protein) into the circulation, where it can clog the renal tubules and cause acute renal failure. Although the exact pathophysiologic mechanisms are unknown, it is suspected that myoglobin has a direct toxic effect on the kidney. Damaged muscle cells also release potassium, which cannot be excreted because of the renal failure. The resulting hyperkalemia may cause dysrhythmias and cardiac arrest.

Crush Syndrome. Crush syndrome (CS) occurs from an external crush injury that compresses one or more compartments in the leg, arm, or pelvis. It is a potentially life-threatening, systemic complication that results from hemorrhage and edema after a severe fracture injury. As muscle becomes ischemic and necrotic from pressure within the compartment, myoglobin is released into circulation, where it can occlude the distal renal tubules and result in kidney failure.

Specific causes of CS include:

- Twisting-type injuries
- Natural disasters, such as earthquakes
- Work-related injuries, such as being trapped under heavy equipment such as a car
- Drug or alcohol overdose, when one or more limbs may be compressed by body weight for a prolonged time
- Older adults who fall, are unable to get up, and lie for a prolonged time

Regardless of the cause, CS is indicated by:

- Acute compartment syndrome
- Hypovolemia (decreased circulating blood volume)
- Hyperkalemia (increased serum potassium)
- **Rhabdomyolysis** (myoglobin release from skeletal muscle into the bloodstream)
- Acute tubular necrosis (ATN) resulting from hypovolemia and rhabdomyolysis
- Dark brown urine
- Muscle weakness and pain

Management focuses on preventing (1) ATN from myoglobin release and (2) cardiac dysrhythmias related to hyperkalemia. Kayexalate may reduce serum potassium adequately, but hemodialysis may be required if potassium levels remain high or kidney failure occurs.

Hypovolemic Shock. Bone is very vascular. Therefore there is a risk for bleeding with bone injury. In addition, trauma can cut nearby arteries and cause hemorrhage, resulting in rapidly developing hypovolemic shock. (The pathophysiology of hypovolemic shock is described in [Chapter 39](#).)

Fat Embolism Syndrome. **Fat embolism syndrome (FES)** is another serious complication in which fat globules are released from the yellow bone marrow into the bloodstream within 12 to 48 hours after an injury or other illness. These globules clog small blood vessels that supply vital organs, most commonly the lungs, and impair organ perfusion. FES usually results from long bone fractures or fracture repair but occasionally is seen in patients who have a total

CHART 54-2 KEY FEATURES

Pulmonary Emboli: Fat Embolism Versus Blood Clot Embolism

FAT EMBOLISM	BLOOD CLOT EMBOLISM
Definition Obstruction of the pulmonary vascular bed by fat globules	Obstruction of the pulmonary artery by a blood clot or clots
Origin 95% from fractures of the long bones; occurs usually within 48 hr of injury	85% from deep vein thrombosis in the legs or pelvis; can occur anytime
Assessment Findings Altered mental status (earliest sign) Increased respirations, pulse, temperature Chest pain Dyspnea Crackles Decreased SaO ₂ Petechiae (50%-60%) Retinal hemorrhage (not common) Mild thrombocytopenia	Same as for fat embolism, except no petechiae
Treatment Bedrest Gentle handling Oxygen Hydration (IV fluids) Possibly steroid therapy Fracture immobilization	Preventive measures (e.g., leg exercises, antiembolism stockings, SCDs) Bedrest Oxygen Possibly mechanical ventilation Anticoagulants Thrombolytics Possible surgery: pulmonary embolectomy, vena cava umbrella

SaO₂, Arterial oxygen saturation; SCD, sequential compression device.

joint replacement. It may also occur, although less often, in those with pancreatitis, osteomyelitis, blunt trauma, or sickle cell disease.

The problem can occur at any age or in either gender, but young men between ages 20 and 40 years and older adults between ages 70 and 80 years are at the greatest risk. Patients with fractured hips have the highest risk, but FES is also common in those with fractures of the pelvis.

The earliest manifestation of FES is altered mental status, which is caused by a low arterial oxygen level. Dyspnea and chest pain may follow. Petechiae, a macular, measles-like rash, may appear over the neck, upper arms, or chest and abdomen. This rash is a classic manifestation but can be a late sign.

Abnormal laboratory findings include:

- Increased erythrocyte sedimentation rate (ESR)
- Decreased serum calcium levels
- Decreased red blood cell and platelet counts
- Increased serum lipase level

These changes in blood values are poorly understood, but they aid in diagnosis of the condition.

FES can result in respiratory failure or death, often from pulmonary edema. When the lungs are affected, the

complication may be misdiagnosed as a pulmonary embolism from a blood clot (Chart 54-2).

Venous Thromboembolism. Venous thromboembolism (VTE) includes deep vein thrombosis (DVT) and its major complication, pulmonary embolism (PE). It is the most common complication of lower extremity surgery or trauma and the most often fatal complication of musculoskeletal surgery. Factors that make patients with fractures most likely to develop VTE include:

- Cancer or chemotherapy
- Surgical procedure longer than 30 minutes
- History of smoking
- Obesity
- Heart disease
- Prolonged immobility
- Oral contraceptives or hormones
- History of VTE complications
- Older adults (especially with hip fractures)

The pathophysiology and management of VTE is described in Chapter 38.

Infection. Whenever there is trauma to tissues, the body's defense system is disrupted. Wound infections are the most common type of infection resulting from orthopedic trauma. They range from superficial skin infections to deep wound abscesses. Infection can also be caused by implanted hardware used to repair a fracture surgically, such as pins, plates, or rods. Clostridial infections can result in gas gangrene or tetanus and can prevent the bone from healing properly.

Bone infection, or **osteomyelitis**, is most common with open fractures in which skin integrity is lost and after surgical repair of a fracture. For patients experiencing this type of trauma, the risk for hospital-acquired infections is increased. These infections are common, and many are from multidrug-resistant organisms, such as methicillin-resistant *Staphylococcus aureus* (MRSA). Reducing MRSA infections is a primary desired outcome for all health care agencies.

Chronic Complications. Ischemic necrosis and delayed bone healing are later complications of musculoskeletal trauma. **Ischemic necrosis** is sometimes referred to as **aseptic** or **avascular necrosis (AVN)** or **osteonecrosis**. Blood supply to the bone is disrupted, leading to the death of bone tissue. This problem is most often a complication of hip fractures or any fracture in which there is displacement of bone. Surgical repair of fractures also can cause necrosis because the hardware can interfere with circulation. Patients on long-term corticosteroid therapy, such as prednisone, are also at high risk for ischemic necrosis.

Delayed union is a fracture that has not healed within 6 months of injury. Some fractures never achieve union; that is, they never completely heal (*nonunion*). Others heal incorrectly (*malunion*). These problems are most common in patients with tibial fractures, fractures that involve many treatment techniques (e.g., cast, traction), and pathologic fractures. Union may also be delayed or not achieved in the older patient. If bone does not heal, he or she typically has chronic pain and immobility from deformity.

Etiology and Genetic Risk

The primary cause of a fracture is trauma from a motor vehicle crash or fall, especially in older adults. The trauma may be a direct blow to the bone or an indirect force from muscle contractions or pulling forces on the bone. Sports,

vigorous exercise, and malnutrition are contributing factors. Bone diseases, such as osteoporosis, increase the risk for a fracture in older adults (see [Chapter 53](#)). Genetic factors that increase risk for fracture are discussed with these specific health problems throughout this text.

Incidence/Prevalence

The incidence of fractures depends on the location of the injury. Rib fractures are the most common type in the adult population. Femoral shaft fractures occur most often in young and middle-aged adults. The incidence of proximal femur (hip) fractures is highest in older adults. Humeral fractures are common in adults; the older the person, usually the more proximal is the fracture. Wrist (Colles') fractures are typically seen in middle and late adulthood and usually result from a fall.

Health Promotion and Maintenance

Airbags and seat belts have decreased the number of severe injuries and deaths, but they have increased the number of leg and ankle fractures, especially in older adults. Encourage people to use seat belts, and support legislation for improved vehicle design and re-evaluation of the federal standards for motor vehicle safety. Health teaching should also focus on other risks for musculoskeletal injury, including:

- Osteoporosis screening and education
- Fall prevention
- Home safety assessment and modification, if needed
- Dangers of drinking and driving
- Drug safety (prescribed, over-the-counter, and illicit)
- Older adults and driving
- Helmet use when riding bicycles, motorcycles, all-terrain vehicles (ATVs), and skateboards

These educational interventions are discussed throughout this book and in other texts. Fall prevention is discussed in detail in [Chapter 3](#) as part of care for older adults.

PATIENT-CENTERED COLLABORATIVE CARE

ASSESSMENT

History

If the patient is in severe pain, delay the interview until he or she is more comfortable. Then, ask about the cause of the fracture, which helps in developing an individualized plan of care. Some type of force, such as incisional, crush, acceleration or deceleration, and shearing and friction, leads to most musculoskeletal injuries. As a result, several body systems are often affected.

Incisional injuries, as from a knife wound, and *crush* injuries cause hemorrhage and decrease blood flow to major organs. *Acceleration or deceleration* injuries cause direct trauma to the spleen, brain, and kidneys when these organs are moved from their fixed locations in the body. *Shearing and friction* damage the skin and cause a high level of wound contamination.

Asking about the events leading to the injury helps identify which forces have been experienced and therefore which body systems or parts of the body to assess. For example, a forward fall often results in Colles' fracture of the wrist because the person tries to catch himself or herself with an outstretched hand. Knowing the mechanism of injury also

helps determine whether other types of injury, such as head and spinal cord injury, might be present.

A drug history, including substance abuse, is important regardless of the patient's age. For example, a young adult may have had an excessive amount of alcohol, which contributed to a motor vehicle crash or to a fall at the work site. Many older adults also consume alcohol and an assortment of prescribed and over-the-counter drugs, which can cause dizziness and loss of balance.

A medical history may identify possible causes of the fracture and gives clues as to how long it will take for the bone to heal. Certain diseases such as bone cancer and Paget's disease cause pathologic fractures that often do not achieve total healing or union.

Ask about the patient's occupation and recreational activities. Some occupations are more hazardous than others. For instance, construction work is potentially more physically dangerous than office work. Certain hobbies and recreational activities are also extremely hazardous, such as skiing. Contact sports, such as football and ice hockey, often result in musculoskeletal injuries, including fractures. Other activities do not have such an obvious potential for injury but can cause fractures nonetheless. For instance, daily jogging or running can lead to fatigue fractures.

Physical Assessment/Clinical Manifestations

The patient with a fracture often has trauma to other body systems. Therefore assess all major body systems *first* for life-threatening complications, including head, chest, and abdominal trauma. For example, some fractures can cause internal organ damage resulting in hemorrhage. When a pelvic fracture is suspected, assess vital signs, skin color, and level of consciousness for indications of possible hypovolemic shock. Check the urine for blood, which indicates possible damage to the urinary system, often the bladder. If the patient cannot void, suspect that the bladder or urethra has been damaged. Complete assessment of these areas is described elsewhere in this text.

! NURSING SAFETY PRIORITY

Action Alert

The most common manifestation of fractures is moderate to often severe pain. Patients with severe or multiple fractures of the arms, legs, or pelvis have severe pain. Vertebral compression fractures are also extremely painful. Patients with a fractured hip may have groin pain or pain referred to the back of the knee or lower back. Pain is usually due to muscle spasm and edema, which result from the fracture. Patients with one or more fractured ribs have severe pain when they take deep breaths. Monitor respiratory status, which may be severely compromised from pain or pneumothorax (air in the pleural cavity). Assess the patient's pain level and manage pain *before* continuing the physical assessment.

For fractures of the shoulder and upper arm, the physical assessment is best done with the patient in a sitting or standing position, if possible, so that shoulder drooping or other abnormal positioning can be seen. Support the affected arm and flex the elbow to promote comfort during the assessment. For more distal areas of the arm, perform the assessment with the patient in a supine position so that the extremity can be elevated to reduce swelling.

Place the patient in a supine position for assessment of the legs and pelvis. A patient with an impacted hip fracture may

be able to walk for a short time after injury, although this is not recommended.

When inspecting the site of a possible fracture, look for a change in bone alignment. The bone may appear deformed, a limb may be internally or externally rotated, and/or one or more bones may also be dislocated (out of their joint capsules). Observe for extremity shortening or a change in bone shape.

If the skin is intact (closed fracture), the area over the fracture may be **ecchymotic** (bruised) from bleeding into the underlying soft tissues. **Subcutaneous emphysema**, the appearance of bubbles under the skin because of air trapping, may be present but is usually seen later.

Swelling at the fracture site is rapid and can result in marked neurovascular compromise. *Gently perform a thorough neurovascular assessment, and compare extremities. Assess skin color and temperature, sensation, mobility, pain, and pulses distal to the fracture site. If the fracture involves an extremity and the patient is not in severe pain, check the nails for capillary refill by applying pressure to the nail and observing for the speed of blood return. If nails are brittle or thick, assess the skin next to the nail. Checking for capillary refill is not as reliable as other indicators of perfusion.* Chart 54-3 describes the procedure for a neurovascular assessment, which evaluates circulation, movement, and sensation (CMS function).

DECISION-MAKING CHALLENGE

Patient-Centered Care; Evidence-Based Practice

A 68-year-old woman slipped on ice on her walkway to her driveway. Her neighbor, an RN, was awakened by her scream for help and rushed to find the woman holding her deformed and swollen ankle. The nurse called 911, performed a rapid head-to-toe assessment, and stayed with her, trying to make her as comfortable as possible. The woman is alert and has no other apparent injury or problem. Upon arrival at the emergency department (ED), another nurse and you greet the patient and help her transfer into a room reserved for her.

1. What are your priority assessments for the patient when coming into the ED? What sources of evidence would you seek to answer this clinical question?
2. The patient has a dislocated ankle (distal tibia and fibula) and reports that she is still in pain even though the EMT gave her IV fentanyl. How will you respond to this patient, and what action will you take?
3. The patient's daughter comes to the ED and asks you if her mother's history of osteopenia may have caused the fracture. How will you answer her?
4. What factors may have contributed to this patient's "slip and fall?"

Psychosocial Assessment

The psychosocial status of a patient with a fracture depends on the extent of the injury, possible complications, coping ability, and the availability of support systems. Hospitalization is not required for a single, uncomplicated fracture, and the patient returns to usual daily activities within a few days. Examples include a single fracture of a finger, wrist, foot, or toe.

In contrast, a patient suffering severe or multiple traumas may be hospitalized for weeks and may undergo many surgical procedures, treatments, and prolonged rehabilitation. These disruptions in lifestyle can create a high level of stress.

The stresses that result from a long-term condition affect relationships between the patient and family members or

CHART 54-3 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Assessment of Neurovascular Status in Patients with Musculoskeletal Injury

ASSESSMENT METHOD	NORMAL FINDINGS
Skin Color Inspect the area distal to the injury.	No change in pigmentation compared with other parts of the body.
Skin Temperature Palpate the area distal to the injury (the dorsum of the hands is most sensitive to temperature).	The skin is warm.
Movement Ask the patient to move the affected area or the area distal to the injury (active motion). Move the area distal to the injury (passive motion).	The patient can move without discomfort. No difference in comfort compared with active movement.
Sensation Ask the patient if numbness or tingling is present (paresthesia). Palpate with a paper clip (especially the web space between the first and second toes or the web space between the thumb and forefinger).	No numbness or tingling. No difference in sensation in the affected and unaffected extremities. (Loss of sensation in these areas indicates peroneal nerve or median nerve damage.)
Pulses Palpate the pulses distal to the injury.	Pulses are strong and easily palpated; no difference in the affected and unaffected extremities.
Capillary Refill (Least Reliable) Press the nail beds distal to the injury until blanching occurs (or the skin near the nail if nails are thick and brittle).	Blood returns (return to usual color) within 3 sec (5 sec for older patients).
Pain Ask the patient about the location, nature, and frequency of the pain.	Pain is usually localized and is often described as stabbing or throbbing. (Pain out of proportion to the injury and unrelieved by analgesics might indicate compartment syndrome.)

friends. Assess the patient's feelings, and ask how he or she coped with previously experienced stressful events. Body image and sexuality may be altered by deformity, treatment modalities for fracture repair, or long-term immobilization. Assess the availability of support systems, such as family, church, or community groups who can help patients during the acute and rehabilitation phases needed when multiple or severe fractures occur. Active patients of any age or those who are older and live alone may become depressed during the healing process. Acute and chronic pain can decrease energy levels and may also cause sadness or depression.

Laboratory Assessment

No special laboratory tests are available for assessment of fractures. Hemoglobin and hematocrit levels may often be low because of bleeding caused by the injury. If extensive soft-tissue damage is present, the erythrocyte sedimentation rate (ESR) may be elevated, which indicates the expected inflammatory response. If this value increases during fracture healing, the patient may have a bone infection. During the healing stages, serum calcium and phosphorus levels are often increased as the bone releases these elements into the blood.

Imaging Assessment

The health care provider requests standard x-rays and tomograms to confirm a diagnosis of fracture. These reveal the bone disruption, malalignment, or deformity. If the x-ray does not show a fracture but the patient is symptomatic, the x-ray is usually repeated with additional views.

The computed tomography (CT) scan is useful in detecting fractures of complex structures, such as the hip and pelvis. It also identifies compression fractures of the spine. Magnetic resonance imaging (MRI) is useful in determining the amount of soft-tissue damage that may have occurred with the fracture.

ANALYSIS

The most common problems for patients with fractures are:

1. Acute Pain related to one or more fractures, soft-tissue damage, muscle spasm, and edema
2. Potential for neurovascular compromise related to tissue edema and/or bleeding
3. Potential for infection related to a wound caused by an open fracture
4. Impaired Physical Mobility related to acute or chronic pain

PLANNING AND IMPLEMENTATION

Managing Acute Pain

Planning: Expected Outcomes. The patient with a fracture is expected to state that he or she has adequate pain control after fracture reduction and immobilization.

Interventions. A fracture can happen anywhere and may be accompanied by multiple injuries to vital organs. Patient-centered collaborative care depends on the severity and extent of the injury and the number of fractures the patient has.

Emergency Care: Fracture. For any patient who experiences trauma in the community, first call 911 and assess for airway, breathing, and circulation (ABCs, or primary survey). Then provide lifesaving care if needed before being concerned about the fracture (Chart 54-4). If CPR is needed, ensure circulation first, followed by airway and breathing (see Chapter 36).

If the person is clothed, cut away clothing from the fracture site, and remove any jewelry from the affected extremity. Control any bleeding by direct pressure on the area and digital pressure over the artery above the fracture. To prevent shock, place the patient in a supine position and keep him or her warm.

After a head-to-toe assessment (secondary survey) and patient stabilization by the prehospital team, pain is managed with IV opioids such as fentanyl. Cardiac monitoring for patients who are older than 50 years is established before drug administration. To prevent further tissue damage, reduce

CHART 54-4 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Emergency Care of the Patient with an Extremity Fracture

1. Assess the patient's airway, breathing, and circulation, and perform a quick head-to-toe assessment.
2. Remove the patient's clothing (cut if necessary) to inspect the affected area while supporting the area above and below the injury. Do not remove shoes because this can cause increased trauma.
3. Remove jewelry on the affected extremity in case of swelling.
4. Apply direct pressure on the area if there is bleeding and pressure over the proximal artery nearest the fracture.
5. Keep the patient warm and in a supine position.
6. Check the neurovascular status of the area distal to the fracture, including temperature, color, sensation, movement, and capillary refill. Compare affected and unaffected limbs.
7. Immobilize the extremity by splinting; include joints above and below the fracture site. Recheck circulation after splinting.
8. Cover any open areas with a dressing (preferably sterile).

pain, and increase circulation, the prehospital or emergency team immobilizes the fracture by splinting. An air splint or any object or device that extends to the joints above and below the fracture to immobilize it can be used as a **splint**. Sterile gauze is placed loosely over open areas to prevent further contamination of the wound.

In the emergency department (ED), physician's office, or urgent care center, fracture management begins with reduction and immobilization of the fracture, while attending to continued pain assessment and management.

Reduction, or realignment of the bone ends for proper healing, is accomplished by a closed method or an open (surgical) procedure. In some cases, dislocated bones are also reduced, such as when the distal tibia and fibula are dislocated with a fractured ankle. Immobilization is achieved by the use of bandages, casts, traction, internal fixation, or external fixation.

The health care provider selects the treatment method based on the type, location, and extent of the fracture. These interventions prevent further injury and reduce pain.

Nonsurgical Management. Nonsurgical management includes closed reduction and immobilization with a bandage, splint, cast, or traction. For some small, closed bone fractures in the hand or foot, reduction is not required. Immobilization with an orthotic device or special orthopedic shoe or boot may be the only management during the healing process.

For each modality, the primary nursing concern is assessment and prevention of neurovascular dysfunction or compromise. Assess the patient's neurovascular status every hour for the first 24 hours and every 1 to 4 hours thereafter, depending on the injury (see Chart 54-3). The patient usually reports discomfort that is unrelieved by analgesics if the bandage, splint, or cast is too tight. Elevate the fractured extremity higher than the heart, and apply ice for the first 24 to 48 hours as needed to reduce edema.

Closed Reduction and Immobilization. Closed reduction is the most common nonsurgical method for managing a simple fracture. While applying a manual pull, or traction, on the bone, the health care provider moves the bone ends so that they realign. Moderate sedation and/or analgesia is often

FIG. 54-3 A universal wrist and forearm splint used for immobilization.

used during this procedure to decrease pain. An x-ray shows that the bone ends are approximated (aligned) before the bone is immobilized.

Bandages and Splints. For certain areas of the body, such as the scapula (shoulder) and clavicle (collarbone), an elastic bandage or commercial immobilizer may be used to keep the bone in place during healing. Because upper extremity bones do not bear weight, splints may be sufficient to keep bone fragments in place for a closed fracture. **Fig. 54-3** shows a wrist splint for fracture immobilization. Thermoplastic, a durable, flexible material for splinting, allows custom fitting to the patient's body part. Splints for lower extremities are also custom-fitted using flexible materials and held in place with elastic bandages (e.g., ace wrap).

Casts. For more complex fractures or fractures of the lower extremity, the physician or orthopedic technician applies a cast to hold bone fragments in place after reduction. A **cast** is a rigid device that immobilizes the affected body part while allowing other body parts to move. It also allows early mobility and reduces pain. Although its most common use is for fractures, a cast may be applied for correction of deformities (e.g., clubfoot) or for prevention of deformities (e.g., those seen in some patients with rheumatoid arthritis).

Several types of materials are used to make casts. The traditional plaster-of-Paris cast is no longer commonly used for management of most fractures. It requires application of a well-fitted stockinette under the material. If the stockinette is too tight, it may impair circulation. If it is too loose, wrinkles can lead to the development of pressure ulcers. Padding is applied over the stockinette, followed by wet plaster rolls wrapped around the extremity or other body part. The cast feels hot because an immediate chemical reaction occurs, but it soon becomes damp and cool. This type of cast takes 24 to 72 hours to dry, depending on the size and location of the cast. A wet cast feels cold, smells musty, and is grayish. The cast is dry when it feels hard and firm, is odorless, and has a shiny white appearance.

If the skin under the cast is open, the health care provider, orthopedic technician, or specially trained nurse cuts a window in the cast so that the wound can be observed and cared for. The piece of cast removed to make the window must be retained and replaced after wound care to prevent localized edema in the area. This is most important when a window is cut from a cast on an extremity. Tape or elastic bandage wrap may be used to keep the "window" in place. A window is also an access for taking pulses, removing wound drains, or preventing abdominal distention when the patient is in a body or spica cast.

FIG. 54-4 Application of fiberglass synthetic cast.

If the cast is too tight, it may be cut with a cast cutter to relieve pressure or allow tissue swelling. The health care provider may choose to **bivalve** the cast (i.e., cut it lengthwise into two equal pieces) if bone healing is almost complete. Either half of the cast can be removed for inspection or for provision of care. The two halves are then held in place by an elastic bandage wrap.

Synthetic materials for casts are much more common and include fiberglass and polyester-cotton knit (**Fig. 54-4**). These materials are lighter than plaster and require minimal drying time. Fiberglass casts are dry in 10 to 15 minutes and can bear weight 30 minutes after application. Polyester-cotton knit casts take 7 minutes to dry and can withstand weight bearing in about 20 minutes. Some health care providers may use synthetic casts for upper extremities and plaster-of-Paris casts for lower extremities because plaster casts can bear more weight for a longer time. However, newer synthetic materials are stronger than earlier ones. Synthetic casts can be bivalved as needed.

Casts can be generally divided into four main groups: arm casts, leg casts, cast braces, and body or spica casts. **Table 54-1** describes specific casts that are used for various parts of the body.

When a patient is in bed with an *arm cast*, teach him or her to elevate the arm above the heart to reduce swelling. The hand should be higher than the heart. Ice may be prescribed for the first 24 to 48 hours. When the patient is out of bed, the arm is supported with a sling placed around the neck to alleviate fatigue caused by the weight of the cast. The sling should distribute the weight over a large area of the shoulders and trunk, not just the neck. Some health care providers prefer that the patient not use a sling after the first few days in an arm cast, particularly a short-arm cast. This encourages normal movement of the mobile joints and enhances bone healing.

A *leg cast* allows mobility and requires the patient to use ambulatory aids such as crutches. A cast shoe, sandal, or boot that attaches to the foot or a rubber walking pad attached to the sole of the cast assists in ambulation (if weight bearing is allowed) and helps prevent damage to the cast. Teach the patient to elevate the affected leg on several pillows to reduce swelling and to apply ice for the first 24 hours or as prescribed.

TABLE 54-1 TYPES OF CASTS USED FOR MUSCULOSKELETAL TRAUMA

TYPE AND CHARACTERISTICS OF CAST	USE
Upper Extremity Casts	
Short-arm cast (SAC) (extends from below the elbow to and including part of the hand)	Stable fractures of the wrist (metacarpals, carpals, or distal radius)
Long-arm cast (LAC) (includes the upper arm to and including part of the hand)	Unstable fractures of the wrist, distal humerus, radius, or ulna
Hanging-arm cast (same as LAC but heavier, with added loop at the mid-forearm)	Fractures of the humerus that cannot be aligned by LAC (light traction is possible while the patient is in bed or by an attached strap that extends around the neck)
Thumb spica (gauntlet) cast (similar to SAC with the thumb casted in abduction)	Fractures of the thumb
Shoulder spica cast (the shoulder is casted in abduction with the elbow flexed)	Unstable fractures of the shoulder girdle or humerus; dislocations of the shoulder
Lower Extremity Casts	
Short-leg cast (SLC) (from below the knee to the base of the toes)	Fractures of the ankle, metatarsals, or foot
Long-leg cast (LLC) (from the mid-upper thigh to the base of the toes)	Unstable fractures of the tibia, fibula, or ankle
Walking cast (a walking device on the bottom of SLC or LLC)	Same as for SLC or LLC
Leg cylinder (similar to SLC, but the ankle and foot are not casted)	Stable fractures of the tibia, fibula, or knee
Long-leg cylinder (similar to LLC, but the ankle and foot are not casted)	Stable fractures of the distal femur, proximal tibia, or knee
Cast Braces (or Brace Casts) (Not As Common)	
Patellar weight-bearing cast (similar to SLC or leg cylinder)	Mid-shaft or distal shaft fractures of the femur
External polycentric knee hinge cast (a hinge connects the lower and upper leg and allows 90 degrees of knee flexion)	Same as for the patellar weight-bearing cast
Body Casts (Not As Common)	
Hip spica (extends from below the nipple line down the affected leg [single], down the leg and half of the unaffected leg [1½], or down both legs [double])	Dislocation of the hip; pelvic or hip injuries
Risser cast (the body jacket extends from the shoulders to beyond the iliac crests and hips, with a large opening over the anterior chest)	Scoliosis; thoracic spinal fractures
Halo cast (the body jacket contains a halo brace)	Fractures of the cervical spine

A *body cast* encircles the trunk of the body and is not commonly used for adults. A **spica cast** encases a portion of the trunk and one or two extremities. A patient with either of these casts presents a special challenge for nursing care. Potential complications related to severe impairment in mobility include:

- Skin breakdown
- Respiratory dysfunction, such as pneumonia and atelectasis
- Constipation
- Joint contractures

Cast syndrome (superior mesenteric artery syndrome), an uncommon but serious complication, may be seen in orthopedic patients who have been placed in a hip spica or body cast. Partial or complete upper intestinal obstruction results in classic symptoms: abdominal distention, epigastric pain, nausea, and vomiting. The vomiting often occurs after meals, and patients may have normal bowel sounds. Partial obstruction occurs initially from compression of the third portion of the duodenum between the superior mesenteric artery and the aorta. This can progress to complete obstruction from duodenal edema caused by continued vomiting and distention. Placing a window in the abdominal portion of the cast or bivalving the cast may be sufficient to prevent or relieve pressure on the duodenum. Management of intestinal obstruction is the same as for any patient with this complication.

Before the cast is applied, explain the purpose of the cast and the procedure for its application. With a plaster cast,

warn the patient about the heat that will be felt immediately after the wet cast is applied. Do not cover the new cast. Allow for air-drying.

! NURSING SAFETY PRIORITY

Action Alert

When moving a patient with a wet plaster cast, handle it with the palms of the hands to prevent indentations and resulting areas of pressure on the skin. Turn the patient every 1 to 2 hours to allow air to circulate and dry all parts of the cast. Be sure to remind unlicensed assistive personnel (UAP) and the family that the cast is wet and requires special handling. If the health care provider requests that the cast be elevated to reduce swelling, use a cloth-covered pillow instead of one encased in plastic, which could cause the cast to retain heat and prevent drying. Elevation of the casted extremity reduces edema but may impair arterial circulation to the affected limb. Therefore performing a neurovascular assessment of the limb distal to (below) the cast is very important.

For preventing contamination by urine or feces, the perineal area of a dry long-leg or body cast may be covered in plastic. Fracture pans are preferred over traditional bedpans because they are smaller and more comfortable. Remind UAP to take care to prevent spillage onto the cast.

Once the plaster cast is dry, inspect it at least once every 8 hours for drainage, cracking, crumbling, alignment, and fit. Plaster casts act like sponges and absorb drainage, whereas synthetic casts act like a wick pulling drainage away from

! NURSING SAFETY PRIORITY**Action Alert**

Check to ensure that any type of cast is not too tight, and frequently monitor neurovascular status, usually every hour for the first 24 hours after application if the patient is hospitalized. You should be able to insert a finger between the cast and the skin. Teach the patient to apply ice for the first 24 to 36 hours to reduce swelling and inflammation.

the drainage site. Padding can also absorb wound drainage. Document the presence of any drainage on the cast. However, the evidence is not clear on whether drainage should be circled on the cast because it may increase anxiety and is not a reliable indicator of drainage amount. *Immediately report to the health care provider any sudden increases in the amount of drainage or change in the integrity of the cast.* After swelling decreases, it is not uncommon for the cast to become too loose and need replacement. If the patient is not admitted to the hospital, provide instructions regarding cast care.

During hospitalization, assess for other complications resulting from casting that can be serious and life threatening, such as infection, circulation impairment, and peripheral nerve damage. If the patient returns home after cast application, teach him or her how to monitor for these complications and when to notify the health care provider.

Infection most often results from the breakdown of skin under the cast (pressure necrosis). If pressure necrosis occurs, the patient typically reports a very painful “hot spot” under the cast and the cast may feel warmer in the affected area. Teach the patient or family to smell the area for mustiness or an unpleasant odor that would indicate infected material. If the infection progresses, a fever may develop.

Circulation impairment and peripheral nerve damage can result from tightness of the cast. Teach the patient to assess for circulation at least daily, including the ability to move the area distal to the extremity, numbness, and increased pain.

The patient with a cast may be immobilized for a prolonged period, depending on the extent of the fracture and the type of cast. Assess for complications of immobility, such as skin breakdown, pneumonia, atelectasis, thromboembolism, and constipation. Before the cast is removed, inform the patient that the cast cutter will not injure the skin but that heat may be felt during the procedure.

Because of prolonged immobilization, a joint may become contracted, usually in a fixed state of flexion. Osteoarthritis and osteoporosis may develop from lack of weight bearing. Muscle can also atrophy from lack of exercise during prolonged immobilization of the affected body part, usually an extremity.

Traction. **Traction** is the application of a pulling force to a part of the body to provide reduction, alignment, and rest. It is also used as a last resort to decrease muscle spasm (thus relieving pain) and prevent or correct deformity and tissue damage. A patient in traction is often hospitalized, but in some cases, home care is possible even for skeletal traction.

Mechanical traction can be either:

- Continuous, as in fracture treatment
- Intermittent, for relief of muscle spasm in other types of musculoskeletal/neurologic trauma, such as cervical nerve root compression

TABLE 54-2 TYPES OF TRACTION USED FOR MUSCULOSKELETAL TRAUMA

TYPE AND CHARACTERISTICS OF TRACTION	USE
Upper Extremity Traction	
Sidearm skin or skeletal traction (the forearm is flexed and extended 90 degrees from the upper part of the body)	Fractures of the humerus with or without involvement of the shoulder and clavicle
Overhead or 90-90 traction, skin or skeletal (the elbow is flexed and the arm is at a right angle to the body over the upper chest)	Same as above (depends on the physician's preference)
Plaster traction (pins inserted through the bone are fixed in the cast)	Fractures of the wrist
Lower Extremity Traction	
Buck's extension traction (skin) (the affected leg is in extension)	Fractures of the hip or femur preoperatively Prevention of hip flexion contractures Hip dislocation
Russell's traction (similar to Buck's traction, but a sling under the knee suspends the leg)	Fractures of the hip or distal end of the femur
Balanced skin or skeletal traction (the limb is usually elevated in a Thomas splint with Pearson's attachment, or a Böhler-Braun splint is used)	Fractures of the femur or pelvis (acetabulum)
Spinal Column and Pelvic Traction	
Cervical halter (a strap under the chin)	Cervical muscle spasms, strain/sprain, or arthritis
Cervical skeletal (e.g., halo brace, Crutchfield tongs)	Cervical fractures of the spine; muscle spasms
Pelvic belt (a strap around the hips at the iliac crests is attached to weights at the foot of the bed)	Pain, strain, sprain, or muscle spasms in the lower back
Pelvic sling (a wide strap around the hips is attached to an overhead bar to keep the pelvis off the bed)	Pelvic fractures; other pelvic injuries

Traction may also be classified as running traction or balanced suspension. In *running* traction, the pulling force is in one direction and the patient's body acts as countertraction. Moving the body or bed position can alter the countertraction force. *Balanced suspension* provides the countertraction so that the pulling force of the traction is not altered when the bed or patient is moved. This allows for increased movement and facilitates care (Table 54-2).

The two most common types of traction are skin and skeletal traction. *Skin traction* involves the use of a Velcro boot (Buck's traction) (Fig. 54-5), belt, or halter, which is usually secured around the affected leg. The primary purpose of skin traction is to decrease painful muscle spasms that accompany hip fractures. The weight is used as a pulling force and is limited to 5 to 10 pounds (2.3 to 4.5 kg) to prevent injury to the skin.

In *skeletal traction*, pins, wires, tongs (e.g., Crutchfield), or screws are surgically inserted directly into bone. These allow the use of longer traction time and heavier weights—usually 15 to 30 pounds (6.8 to 13.6 kg). Skeletal traction aids in bone

FIG. 54-5 Skin traction with a hook-and-loop fastener (Velcro) boot, commonly used for hip fractures.

realignment. Pin site care is an important part of nursing management to prevent infection.

The nurse may set up or assist in the setup of traction if specially educated. In larger or specialty hospitals or units, orthopedic technicians or physician assistants often set up traction. Once traction is applied, maintain the correct balance between traction pull and countertraction force.

! NURSING SAFETY PRIORITY

Action Alert

When patients are in traction, weights usually are not removed without a prescription. They should not be lifted manually or allowed to rest on the floor. Weights should be freely hanging at all times. Teach this important point to UAP on the unit, to other personnel such as those in the radiology department, and to visitors. Inspect the skin at least every 8 hours for signs of irritation or inflammation. When possible, remove the belt or boot that is used for skin traction every 8 hours to inspect under the device.

Check traction equipment frequently to ensure its proper functioning. Inspect all ropes, knots, and pulleys at least every 8 to 12 hours for loosening, fraying, and positioning. Check the weight for consistency with the health care provider's prescription. Sometimes one of the weights is accidentally removed by a staff member or visitor who bumps into it. Replace the weights if they are not correct, and notify the health care provider or orthopedic technician.

If the patient reports severe pain from muscle spasm, the weights may be too heavy or the patient may need realignment. Report the pain to the health care provider if body realignment fails to reduce the discomfort. Assess neurovascular status of the affected body part to detect circulatory compromise and tissue damage. The circulation is usually monitored every hour for the first 24 hours after traction is applied and every 4 hours thereafter.

? NCLEX EXAMINATION CHALLENGE

Physiological Integrity

A client has a new synthetic arm cast for a radial fracture. What health care teaching does the nurse include for the client's home care?

Select all that apply.

- A. "Apply heat on the cast for the first 24 hours to increase blood flow for healing."
- B. "Keep your arm elevated, preferably above your heart, as much as possible."
- C. "Report severe numbness or inability to move your fingers to your physician."
- D. "Take your pain medication as needed according to the prescription directions."
- E. "Don't cover the cast with anything because it will stay wet for 24 hours."

Drug Therapy. After fracture treatment, the patient often has pain for a prolonged time during the healing process. The health care provider commonly prescribes opioid and non-opioid analgesics, anti-inflammatory drugs, and muscle relaxants.

For patients with chronic, severe pain, opioid and non-opioid drugs are alternated or given together to manage pain both centrally in the brain and peripherally at the site of injury. For severe or multiple fractures, patient-controlled analgesia (PCA) with morphine, fentanyl, or other drug is used. *Meperidine (Demerol) should never be used for older adults because it has toxic metabolites that can cause seizures and other complications. Many hospitals no longer use this drug for patients of any age. Oxycodone and oxycodone with acetaminophen (Percocet) are common oral opioid drugs that are very effective for most patients with fracture pain. NSAIDs are given to decrease associated tissue inflammation.*

For patients who have less severe injury, the analgesic may be given on an as-needed basis. Collaborate with the patient regarding the best times for the strong pain relievers to be given (e.g., before a complex dressing change, after physical therapy sessions, and at bedtime). Assess the effectiveness of the analgesic and its side effects. Constipation is a common side effect of opioid therapy, especially for older adults. Assess for frequency of bowel movements, and administer stool softeners as needed. Encourage fluids and activity as tolerated. **Chapter 5** discusses the various methods of pain management, including epidural analgesia and patient-controlled analgesia.

Some patients experience a long-term, intense burning pain and edema that are associated with *complex regional pain syndrome (CRPS)*, formerly called *reflex sympathetic dystrophy (RSD)*. This syndrome often results from fractures and other musculoskeletal trauma and is discussed on p. 1168 later in this chapter.

Complementary and Alternative Therapies. With long-term, severe pain, the patient cannot depend solely on drugs for relief. Recommend temporary pain relief measures, such as ice or heat, depending on the cause of the pain. If swelling causes pressure on the affected area, ice and elevation of the affected body part may be appropriate. Teach the patient to plan activities that allow for rest and quiet periods. Some patients like soft music playing while resting. Muscle spasms are best relieved by application of heat and massage. Other physical measures include a warm, soothing bath, a back rub, and the use of therapeutic touch.

FIG. 54-6 The Hex-Fix external fixation system for tibia-fibula fractures.

If these measures are not effective in reducing pain, distraction, imagery, or music therapy may be used as an alternative. Teach the patient relaxation techniques, such as deep breathing, for use during periods of severe pain. [Chapters 2 and 5](#) discuss these techniques in detail.

Surgical Management. For some types of fractures, closed reduction is not appropriate or sufficient. Surgical intervention may be needed to realign the bone for the healing process.

Preoperative Care. Teach the patient and family what to expect during and after the surgery. The preoperative care for a patient undergoing orthopedic surgery is similar to that for anyone having surgery with general or epidural anesthesia. (See [Chapter 16](#) for a thorough discussion of preoperative nursing care.)

Operative Procedures. Open reduction with internal fixation (ORIF) is one of the most common methods of reducing and immobilizing a fracture. External fixation with closed reduction is used when patients have soft-tissue injury (open fracture). Although nurses do not decide which surgical technique is used, understanding the procedures enhances patient teaching and care.

Because ORIF permits early mobilization, it is often the preferred surgical method. **Open reduction** allows the surgeon to directly view the fracture site. **Internal fixation** uses metal pins, screws, rods, plates, or prostheses to immobilize the fracture during healing. The surgeon makes one or more incisions to gain access to the broken bone(s) and implants one or more devices into bone tissue after each fracture is reduced. A cast, boot, or splint is placed to maintain immobilization during the healing process.

After the bone achieves union, the metal hardware may be removed, depending on the location and type of fracture. Hardware is removed most frequently in ankle fractures, depending on the severity of the injury. If the metal implants are not bothersome, they may remain in place. Specific types of internal fixation devices are discussed later in the Fractures of Specific Sites section.

An alternative modality for the management of fractures is the external fixation apparatus, as shown in [Fig. 54-6](#). **External fixation** is a system in which pins or wires are inserted through the skin and affected bone and then connected to a rigid external frame. The system may be used for

upper or lower extremity fractures or for fractures of the pelvis, especially for open fractures when wound management is needed. After a fixator is removed, the patient may be placed in a cast or splint until healing is complete.

External fixation has several advantages over other surgical techniques:

- There is minimal blood loss compared with internal fixation.
- The device allows early ambulation and exercise of the affected body part while relieving pain.
- The device maintains alignment in closed fractures that will not maintain position in a cast and stabilizes comminuted fractures that require bone grafting.

In open fractures, in which skin and tissue trauma accompany the fracture, the device permits easy access to the wound while the bone heals. This method is usually preferred over the use of a window in a cast for wound care.

A disadvantage of external fixation is an increased risk for pin site infection. Pin site infections can lead to osteomyelitis, which is serious and difficult to treat (see [Chapter 53](#)).

Postoperative Care. The postoperative care for a patient undergoing ORIF or external fixation is similar to that provided for any patient undergoing surgery (see [Chapter 18](#)). Because bone is a vascular, dynamic body tissue, the patient is at risk for complications specific to fractures and musculoskeletal surgery. IV ketorolac (Toradol) is often given in the postanesthesia care unit (PACU) or soon after discharge to the post-surgical area to reduce inflammation and pain. Aggressive pain management starts as soon as possible after surgery to prevent the development of chronic pain and promote early mobility.

Additional information about postoperative care is found beginning on p. 1159 in the Fractures of Specific Sites section. Depending on the fractures that are repaired, some ORIF procedures are performed as same-day surgeries. Patients stay in the hospital up to 23 hours after surgery.

For patients with an **external fixator**, pay particular attention to the pin sites for signs of inflammation or infection. In the first 48 to 72 hours, *clear* fluid drainage or weeping is expected. Although no standardized method or evidence-based protocol for pin care has been established, recommendations have been made based on the evidence available regarding pin site care. Because the pins go through the skin and into bone, the risk for infection is high. Monitor the pin sites at least every 8 to 12 hours for drainage, color, odor, and severe redness, which indicate inflammation and possible infection. Follow agency policy for how to clean the pin site areas, and ensure that it follows the evidence-based guidelines from the National Association of Orthopaedic Nurses (www.naon.org) (Holmes & Brown, 2005).

The patient with an external fixator may have a disturbed body image. The frame may be large and bulky, and the affected area may have massive tissue damage with dressings. Be sensitive to this possibility in planning care. Teach about alterations to clothing that may be required while the fixator is in place.

The Ilizarov technique of circular external fixation is sometimes used to treat new fractures (closed, comminuted fractures and open fractures with bone loss), as well as malunion or nonunion of fractures. It may also be used to treat congenital bone deformities, especially in children and “little people” (e.g., dwarfs).

The circular external fixation device is used to gently pull apart the cortex of the bone and stimulate new bone growth. Unlike the traditional fixator, the Ilizarov external fixator promotes rotation, angulation, lengthening, or widening of bone to correct bony defects and allows for healing of any soft-tissue defect. The nursing care associated with this device is similar to the care of the patient with other external fixation systems with one major exception. If the device is being used for filling bone gaps using bone transport or distraction, teach the patient how to manually turn the four-sided nuts (also called *clickers*) up to four times a day. Daily distraction rates vary, but 1 mm daily is common. Screening and teaching are particularly important because the patient adjusts and cares for the apparatus over a long period of up to 6 months to 1 year. Pain control is a priority outcome for patients using this device.

Procedures for Nonunion. Some management techniques are not successful because the bone does not heal. Several additional options are available to the physician to promote bone union, such as electrical bone stimulation, bone grafting, and ultrasound fracture treatment.

For selected patients, *electrical bone stimulation* may be successful. This procedure is based on research showing that bone has electrical properties that are used in healing. The exact mechanism of action is unknown. A noninvasive, external **electrical bone stimulation** system delivers a small continuous electrical charge directed toward the non-healed bone. There are no known risks with this system, although patients with pacemakers cannot use this device on an arm. Implanted direct-current stimulators are placed directly in the fracture site and have no external apparatus. Both systems require several months of treatment.

Another method of treating nonunion is *bone grafting*. A bone graft may also replace diseased bone or increase bone tissue for joint replacement. In most cases, chips of bone are taken from the iliac crest or other site and are packed or wired between the bone ends to facilitate union. Allografts from cadavers may also be used. These grafts are frozen or freeze-dried and stored under sterile conditions in a bone bank.

Bone banking from living donors is becoming increasingly popular. If qualified, patients undergoing total hip replacement may donate their femoral heads to the bank for later use as bone grafts for others. Careful screening ensures that the bone is healthy and that the donor has no communicable disease. The bone cannot be donated without written consent.

One of the newest modalities for fracture healing is **low-intensity pulsed ultrasound** (Exogen therapy). Used for slow-healing fractures or for new fractures as an alternative to surgery, ultrasound treatment has had excellent results. The patient applies the treatment for about 20 minutes each day. It has no contraindications or adverse effects.

Physical Therapy. Many patients with musculoskeletal trauma, including fractures, are referred by their health care provider for rehabilitation therapy with a physical therapist (PT). The timing for this referral depends on the nature, severity, and treatment modality of the fracture(s).

For example, some patients who have an ORIF for one or more ankle fractures may begin therapy when the incisional staples or Steri-Strips are removed and an orthopedic knee boot is fitted. Based on the initial evaluation, the PT performs gentle manipulative exercises to increase range of motion.

The therapist may also begin to help the patient with laterality, a concept to help the brain identify the injured foot from the uninjured foot. Computer programs and mirror-box therapy can help reprogram the brain as part of cognitive retraining. In mirror-box therapy for an injured foot, the patient covers his or her affected foot while looking at and moving the uninjured foot in front of the mirror. The brain perceives the foot in the mirror as the injured foot.

Stimulation by touch also helps the brain acknowledge the injured foot. The PT teaches the patient to have someone frequently touch the injured area and use various materials and objects against the skin to desensitize it.

When weight bearing begins about 6 weeks after surgery, the PT teaches the patient how to begin with toe-touch or partial weight bearing using crutches or a walker. Muscle strengthening exercises of the affected leg help with ambulation because atrophy begins shortly after injury.

The PT also assists with pain control and edema reduction by using ice/heat packs, electrical muscle stimulation (“e-stim”), and special treatments such as dexamethasone iontophoresis. **Iontophoresis** is a method for absorbing dexamethasone, a synthetic steroid, through the skin near the painful area to decrease inflammation and edema. A small device delivers a minute amount of electricity via electrodes that are placed on the skin. The patient may describe the sensation as a pinch or slight sting. The current increases the ability of the skin to absorb the drug from a topical patch into the affected soft tissue.

The success of rehabilitation is affected by the patient’s motivation and willingness to perform prescribed exercises and activities between PT visits. Rehabilitation for ankle surgery, for example, may take several months, depending on the severity of the injury and the age and general health condition of the patient.

Preventing and Monitoring for Neurovascular Compromise

Planning: Expected Outcomes. The patient with a fracture is expected to have no compromise in neurovascular status as evidenced by adequate circulation, movement, and sensation (CMS). If severe compromise occurs, the patient is expected to have early and prompt emergency treatment to prevent severe tissue damage.

Interventions. Perform neurovascular (NV) assessments (also known as “circ checks” or CMS assessments) frequently before and after fracture treatment. Patients who have extremity casts, splints with elastic bandage wraps, and open reduction with internal fixation (ORIF) or external fixation are especially at risk for NV compromise. If blood flow to the distal extremity is impaired, the patient reports increased pain and decreased sensation and movement. If these symptoms are allowed to progress, patients are at risk for acute compartment syndrome (ACS).

Early recognition of the signs and symptoms of ACS can prevent loss of function or loss of a limb. Identify patients who may be at risk, and monitor them closely. ACS can begin in 6 to 8 hours after an injury or take up to 2 days to appear. If it is suspected, notify the health care provider immediately, and if possible, implement interventions to relieve the pressure. For example, for the patient with tight, bulky dressings, loosen the bandage or tape. If the patient has a cast, follow agency protocol about who may cut the cast.

! NURSING SAFETY PRIORITY**Critical Rescue**

Monitor for early signs of ACS. Assess for the “six Ps” including **p**ain, **p**ressure, **p**aralysis, **p**aresthesia, **p**allor, and **p**ulselessness (rare). Pain is increased even with passive motion and may seem out of proportion to the degree of injury. Analgesics that had controlled pain become less effective. Numbness and tingling or paresthesias are often one of the first signs of the problem. The affected extremity then becomes pale and cool as a result of decreased arterial perfusion to the affected area. Capillary refill is an important assessment of perfusion but may not be reliable in an older adult because of arterial insufficiency. Losses of movement and function and decreased pulses or pulselessness are late signs of ACS! Fortunately, ACS is not common, but it creates an emergency situation when it does occur.

In a few cases, compartment pressure may be monitored on a one-time basis with a handheld device with a digital display or pressure can be monitored continuously. Monitoring is recommended for comatose or unresponsive high-risk patients with multiple trauma and fractures.

If ACS is verified, the surgeon may perform a **fasciotomy**, or opening in the fascia, by making an incision through the skin and subcutaneous tissues into the fascia of the affected compartment. This procedure relieves the pressure and restores circulation to the affected area. No consensus exists on what pressure requires fasciotomy (normal is 0 to 8 mm Hg). Compartment pressures must be considered in relation to the patient’s hemodynamic status. After fasciotomy, the open wound is packed and dressed daily or more often until secondary closure occurs, usually in 4 to 5 days, depending on the patient’s healing ability. At that time, the surgeon usually débrides the wound and may apply a skin graft to promote healing.

Preventing Infection

Planning: Expected Outcomes. The patient with a fracture is expected to be free of wound or bone infection as evidenced by no fever, no increase in white blood cell count, and negative wound culture (if wound is present).

Interventions. When caring for a patient with an open fracture, use clean or aseptic technique for dressing changes and wound irrigations. Check agency policy for specific protocols. *Immediately notify the health care provider if you observe inflammation and purulent drainage.* Other infections, such as pneumonia and urinary tract infection, may occur several days after the fracture. Monitor the patient’s vital signs every 4 to 8 hours because increases in temperature and pulse often indicate systemic infection.

CONSIDERATIONS FOR OLDER ADULTS

Older adults may not have a temperature elevation even in the presence of severe infection. An acute onset of confusion (delirium) often suggests an infection in the older adult patient.

For most patients with an open fracture, the health care provider prescribes one or more broad-spectrum antibiotics prophylactically and performs surgical débridement of any wounds as soon as possible after the injury. First-generation cephalosporins, clindamycin (Cleocin), and ciprofloxacin (Cipro) are commonly used. In addition to systemic antibiotics, local antibiotic therapy through wound irrigation is commonly prescribed, especially during débridement.

A very effective wound therapy is the vacuum-assisted closure (VAC) system as a method of increasing the rate of wound healing for open fractures. This device allows quicker wound closure, which decreases the risk for infection.

When the bone is surgically repaired, hardware and/or bone grafts have typically been implanted. However, they are limited in their use. The U.S. Food and Drug Administration (FDA) approved the use of recombinant human bone morphogenetic protein-2 (rhBMP-2) for tibial and spinal fractures. This implanted genetically engineered substance increases wound healing, decreases hardware failure, and decreases the risk for infection.

Improving Physical Mobility

Planning: Expected Outcomes. The patient with a fracture is expected to increase physical mobility and be free of complications associated with impaired mobility. The patient is also expected to move purposefully in his or her own environment independently with or without an ambulatory device unless restricted by traction or other modality.

Interventions. The interventions necessary for this diagnosis can be grouped into two types: those that help increase mobility and those that prevent complications of impaired mobility.

Promoting Mobility. The use of crutches or a walker increases mobility and assists in ambulation. The patient may progress to using a walker or cane after crutches.

Crutches are the most commonly used ambulatory aid for many types of lower extremity musculoskeletal trauma (e.g., fractures, sprains, amputations). In most agencies, the physical therapist or emergency department/ambulatory care nurse fits the patient for crutches and teaches him or her how to ambulate with them. Reinforce those instructions, and evaluate whether the patient is using the crutches correctly.

Walking with crutches requires strong arm muscles, balance, and coordination. For this reason, crutches are not often used for older adults. Walkers and canes are preferred for the older adult. Crutches can cause upper extremity bursitis or axillary nerve damage if they are not fitted or used correctly. For that reason, the top of each crutch is padded. To prevent pressure on the axillary nerve, there should be two to three finger breadths between the axilla and the top of the crutch when the crutch tip is at least 6 inches (15 cm) diagonally in front of the foot. The crutch is adjusted so that the elbow is flexed no more than 30 degrees when the palm is on the handle (Fig. 54-7). The distal tips of each crutch are rubber to prevent slipping.

There are several types of gaits for walking with crutches. The most common one for musculoskeletal injury is the three-point gait, which allows little weight bearing on the affected leg. The procedure for these gaits is discussed in fundamentals of nursing books.

A **walker** is most often used by the older patient who needs additional support for balance. The physical therapist assesses the strength of the upper extremities and the unaffected leg. Strength is improved with prescribed exercises as needed.

A **cane** is sometimes used if the patient needs only minimal support for an affected leg. The straight cane offers the least support. A hemi-cane or quad-cane provides a broader base for the cane and therefore more support. The cane is placed on the *unaffected* side and should create no more than 30 degrees of flexion of the elbow. The top of the cane should

FIG. 54-7 Assisting the patient with crutch walking. Note how the therapist guards the patient and how the patient's elbows are at no more than 30 degrees of flexion.

be parallel to the greater trochanter of the femur or styloid of the wrist. [Chapter 8](#) describes these ambulatory devices in more detail.

Preventing Complications of Immobility. The nurse plays a vital role in preventing and assessing for complications in immobilized patients with fractures. Additional information about nursing care for preventing problems associated with immobility is found in [Chapter 8](#).

Community-Based Care

The patient with an *uncomplicated* fracture is usually discharged to home from the emergency department or urgent care center. Older adults with hip or other fractures or patients with multiple traumas are hospitalized and then transferred to home, a rehabilitation setting, or a long-term care facility for rehabilitation. Collaborate with the case manager or the discharge planner in the hospital to ensure continuity of care. Be sure to communicate the plan of care clearly to the health care agency receiving the patient.

Home Care Management

If the patient is discharged to home, the nurse, therapist, or case manager (CM) may assess the home environment for structural barriers to mobility, such as stairs. Be sure that the patient has easy access to the bathroom. Ask about scatter rugs, waxed floors, and walkway areas that could increase the risk for falls. If the patient needs to use a wheelchair or ambulatory aid, make sure that he or she can use it safely and that there is room in the house to ambulate with these devices. The physical therapist may teach the patient how to use stairs, but older adults or those using crutches may experience difficulty performing this task. Depending on the age and condition of the patient, a home health care nurse may make one or two visits to check that the home is safe and that the

CHART 54-5 PATIENT AND FAMILY EDUCATION: PREPARING FOR SELF-MANAGEMENT

Care of the Extremity After Cast Removal

- Remove scaly, dead skin carefully by soaking; do not scrub.
- Move the extremity carefully. Expect discomfort, weakness, and decreased range of motion.
- Support the extremity with pillows or your orthotic device until strength and movement return.
- Exercise slowly as instructed by your physical therapist.
- Wear support stockings or elastic bandages to prevent swelling (for lower extremity).

patient and family are able to follow the interdisciplinary plan of care.

Teaching for Self-Management

The patient with a fracture may be discharged from the hospital, emergency department, office, or clinic with a bandage, splint, cast, or external fixator. Provide verbal and written instructions on the care of these devices. [Chart 54-5](#) describes care of the affected extremity after removal of the cast.

The patient may also need to continue wound care at home. Instruct the patient and family about how to assess and dress the wound to promote healing and prevent infection. Teach them how to recognize complications and when and where to seek professional health care if complications occur. Additional educational needs depend on the type of fracture and fracture repair.

Encourage patients and their families to ensure adequate foods high in protein and calcium that are needed for bone and tissue healing. For patients with lower extremity fractures, less weight bearing on long bones can cause anemia. The red bone marrow needs weight bearing to stimulate red blood cell production. Encourage foods high in iron content. Teach the patient to take a daily iron-added multivitamin (take with food to prevent possible nausea).

Health Care Resources

Arrange for follow-up care at home. A social worker may need to help the patient apply for funds to pay medical bills. If there is severe bone and tissue damage, be realistic and help the patient and family understand the long-term nature of the recovery period. Multiple treatment techniques and surgical procedures required for complications can be mentally and emotionally draining for the patient and family. A vocational counselor may be needed to help the patient find a different type of job, depending on the extent of the fracture.

An older or incapacitated patient may need assistance with ADLs, which can be provided by home care aides if family or other caregiver is not available. In collaboration with the case manager, anticipate the patient's needs and arrange for these services.

EVALUATION: OUTCOMES

Evaluate the care of the patient with one or more fractures based on the identified priority patient problems. The expected outcomes include that the patient:

- States that he or she has adequate pain control
- Has adequate blood flow to maintain tissue perfusion and function
- Is free of infection
- Is free of physiologic consequences of impaired mobility
- Ambulates or moves independently with or without an assistive device (if not restricted by traction or other device)

DECISION-MAKING CHALLENGE

Safety; Evidence-Based Practice; Informatics

The 68-year-old patient with multiple fractures of her ankle presented in the Decision-Making Challenge on p. 1149 needs a joint reduction for her dislocated tibia and fibula. As her nurse, you explain the procedure and assure her that she will not have pain during the procedure. You apply a pulse oximeter, nasal oxygen, and capnography monitoring system in preparation for the procedure.

1. What is the purpose of the capnography system?
2. While the patient receives moderate sedation, you note that her respiratory rate drops to 8 breaths/min and her capnography reading is 18. What do these values mean? What evidence-based action will you take first as a result of these values? What will you document in the electronic patient record about the patient's response during the procedure?
3. After the joint is reduced, a splint and large bulky dressing with elastic wraps are applied. The patient will be going home with her daughter, using crutches. What crutch-walking technique will you teach her?
4. What other health teaching will she need and why?

FRACTURES OF SPECIFIC SITES

Upper Extremity Fractures

In addition to the general care discussed in the previous section, management of upper extremity fractures includes specific interventions related to the location and nature of the injury. Unless multiple fractures or massive soft-tissue damage occurs, upper extremity fractures do not usually require hospitalization. However, they often take many months to heal. In some cases, patients may not regain complete function for up to a year, even after extensive rehabilitation in occupational therapy. Assess neurovascular status in the affected arm and hand before and after fracture treatment. Monitor for numbness and tingling distal to (below) the injury, which may indicate peripheral nerve damage.

Fractures of the *clavicle* typically result from a fall on an outstretched hand, a fall on the shoulder, or a direct blow to the upper chest and shoulder area. Most clavicular fractures are self-healing. A splint or bandage is used for immobilization. Complicated open fractures, although uncommon, may require open reduction with internal fixation (ORIF) by pins, wires, or screws.

Scapular fractures are not common and are usually caused by direct impact to the area. Serious internal trauma, including pneumothorax, pulmonary contusion, and fractured ribs, can accompany these fractures. The shoulder is kept in position with a commercial immobilizer until the fracture heals, usually in 2 to 4 weeks. Intra-articular neck and glenoid fractures may require surgical intervention with plate and screw fixation.

Fractures of the *proximal humerus*, particularly impacted or displaced fractures, are common in the older adult. As

persons age, fractures of the humerus occur more frequently in the area closer to the shoulder joint. This makes treatment more difficult in the older adult. An impacted injury is usually treated with a sling or other device for immobilization. A displaced fracture often requires ORIF with pins or a prosthesis.

Humeral shaft fractures are generally corrected by closed reduction and a hanging-arm cast or splint. If necessary, the fracture is repaired surgically (with an intramedullary rod or metal plate and screws) or with external fixation. Non-union of the bone and radial nerve palsy are frequent complications of this fracture. Bone grafting helps promote union. Prolonged splinting is necessary while the radial nerve regenerates.

A direct blow to the condyles of the distal humerus can cause either or both condyles to fracture, usually in a T- or Y-shaped configuration. The most serious complication is damage to the brachial or median nerve. Condylar fracture is usually treated by ORIF with a series of screws, although skeletal traction and casting can be used.

Fractures of the *elbow (olecranon)* are common in adults and typically result from a fall on the elbow. Many are successfully treated by closed reduction and application of a cast. ORIF is performed for displaced fractures, and a splint is worn during the healing phase.

Forearm fractures of the ulna without accompanying injury to the radius are rare. As with other fractures of long bones, closed reduction with casting may be the appropriate treatment. If the fracture is displaced, ORIF with intramedullary rods or plates and screws is required.

One or more of the bones in the *wrist and hand* can break, but the most common fracture is of the carpal scaphoid bone in young adult men. This is also one of the most misdiagnosed fractures because it is poorly visualized on an x-ray film. Closed reduction and casting for 6 to 12 weeks is the treatment of choice. If the bone does not heal, ORIF with bone grafting is performed.

A *Colles' (wrist)* fracture is common in older adults, particularly women with osteoporosis. A Colles' fracture occurs in the last inch of the distal radius and often is the result of a fall on an outstretched hand. These fractures can usually be treated by splinting or casting for 6 to 8 weeks.

Fractures of the *metacarpals* and *phalanges (fingers)* are usually not displaced, which makes their treatment less difficult than that of other fractures. Metacarpal fractures are immobilized for 3 to 4 weeks. Phalangeal fractures are immobilized in finger splints for 10 to 14 days.

Lower Extremity Fractures

Fractures of the Hip

Hip fracture is the most common injury in older adults and one of the most frequently seen injuries in any health care setting or community. It has a high mortality rate as a result of multiple complications related to surgery, depression, and prolonged immobility. Between 25% and 40% of patients who had a hip fracture die within 1 year after surgery.

Hip fractures include those involving the upper third of the femur and are classified as **intracapsular** (within the joint capsule) or **extracapsular** (outside the joint capsule). These types are further divided according to fracture location (Fig. 54-8). In the area of the femoral neck there is concern with

FIG. 54-8 Types of hip fractures.

disruption of the blood supply to the head of the femur, which can result in ischemic or avascular necrosis (AVN) of the femoral head. AVN causes death and necrosis of bone tissue and results in pain and decreased mobility. This problem is most likely in patients with displaced fractures.

Osteoporosis is the biggest risk factor for hip fractures (see Chapter 53). This disease weakens the upper femur (hip), breaks, and then causes the person to fall. The number of

CONSIDERATIONS FOR OLDER ADULTS

Teach older adults about the risk factors for hip fracture including physiologic aging changes, disease processes, drug therapy, and environmental hazards. Physiologic changes include sensory changes such as diminished visual acuity and hearing; changes in gait, balance, and muscle strength; and joint stiffness. Disease processes like osteoporosis, foot disorders, and changes in cardiac function increase the risk for hip fracture. Drugs, such as diuretics, antihypertensives, antidepressants, sedatives, opioids, and alcohol, are factors that increase the risks for falling in older adults. Use of three or more drugs at the same time drastically increases the risk for falls. Throw rugs, loose carpeting, inadequate lighting, uneven walking surfaces or steps, and pets are environmental hazards that also cause falls.

The older adult with hip fracture usually reports groin pain or pain behind the knee on the affected side. In some cases, the patient has pain in the lower back or has no pain at all. However, the patient is not able to stand. X-ray or other imaging assessment confirms the diagnosis.

FIG. 54-9 A hip prosthesis used for fractures.

FIG. 54-10 A compression hip screw used for open reduction with internal fixation (ORIF) of the hip.

people with hip fracture is expected to continue to increase as the population ages, and the associated health care costs will be tremendous.

The treatment of choice is surgical repair (open reduction, internal fixation, or ORIF), when possible, to reduce pain and allow the older patient to be out of bed and ambulatory. Skin (Buck's) traction may be applied before surgery to help decrease pain associated with muscle spasm. Depending on the exact location of the fracture, an ORIF may include an intramedullary rod, pins, prostheses (for femoral head or neck fractures), or a compression screw. Epidural or general anesthesia is used. Figs. 54-9 and 54-10 illustrate examples of these devices. Occasionally a patient will be so debilitated that surgery cannot be done. In these cases, nonsurgical options include pain management and bedrest to allow natural fracture healing.

Patients usually receive IV morphine after admission to the emergency department and PCA morphine or epidural analgesia after surgery (Herr & Titler, 2009). Meperidine (Demerol) should not be used due to its toxic metabolites that can cause seizures and other adverse drug events, especially in the older adult population (see the Evidence-Based

EVIDENCE-BASED PRACTICE

Do ED Nurses Follow Best Practices for Acute Pain Management for Older Adults with a Fractured Hip?

Herr, K., & Tittler, M. (2009). Acute pain assessment and pharmacological management practices for the older adult with a hip fracture: Review of ED trends. *Journal of Emergency Nursing*, 35(4), 312-320.

The researchers conducted a retrospective review of 1454 older adult patients with hip fractures admitted through the emergency department in 12 acute care hospitals over a 3-year period after The Joint Commission issued new pain assessment and management standards for this population. Pain assessment and management practices were examined for trends over time. Almost all patients had some documentation of pain assessment using either a numeric scale or non-numeric scale (e.g., verbal descriptor or faces scale).

The mean intensity of pain was between 6.8 and 7.2 on a 1-to-10 pain scale. Yet, only 60% of patients had an order for an analgesic. Of those orders, about 90% received an opioid. Practice improvements showed a decline in IM opioid administration and meperidine administration and an increase in IV morphine as the drug of choice. These trends are in line with current best practices but need improvement, especially the need for pain control for patients who have fractures.

Level of Evidence: 4

The study was a large descriptive study that examined medical records for trends in practice.

Commentary: Implications for Practice and Research

This study demonstrates the need for nurses to advocate for their patients for pain control. Pain is the priority problem that patients have when they sustain a fracture. Many health care providers are hesitant to prescribe pain medication for older adults for fear of respiratory depression or other negative outcome. Titrated opioid drugs are safe for older adults when given in the health care setting. Uncontrolled pain can cause delirium and increased anxiety among older adults. If a patient cannot state his or her pain intensity, non-verbal descriptors like grimacing or yelling out validate the presence of pain.

Practice box above). Chapter 5 discusses the nursing care associated with pain management in detail.

After a hip repair, older adults frequently experience acute confusion, or delirium. They may pull at tubes or the surgical dressing or attempt to climb out of bed, possibly falling and causing self-injury. Other patients stay awake all night and sleep during the day. Keep in mind that some patients have a quiet delirium. Monitor the patient frequently to prevent falls. Ask the family or other visitors to let staff know if the patient is attempting to get out of bed. Chapter 3 describes fall prevention strategies and delirium management in detail.

! NURSING SAFETY PRIORITY**Action Alert**

Patients who have an ORIF are at risk for hip dislocation or subluxation. Be sure to prevent hip adduction and rotation to keep the operative leg in proper alignment. Regular pillows or abduction devices can be used for patients who are confused or restless. If straps are used to hold the device in place, check the skin for signs of pressure. Perform neurovascular assessments to ensure that the device is not interfering with arterial circulation or peripheral nerve conduction.

The patient begins ambulating with assistance the day after surgery to prevent complications associated with immobility (e.g., pressure ulcers, atelectasis, venous thromboembolism). Early movement and ambulation also decrease the chance of infection and increase surgical site healing.

Special considerations for the patient having a hip repair also include careful inspection of skin including areas of pressure, especially the heels. Use of skin traction to reduce muscle spasms may increase the period of bedrest before surgery. Decreased mobility after surgery can increase the risk for pressure injury in this area within 24 hours.

! NURSING SAFETY PRIORITY**Action Alert**

Be sure that the patient's heels are up off the bed at all times. Inspect the heels and other high-risk bony prominence areas every 8 to 12 hours. Delegate turning and repositioning every 1 to 2 hours to uncensored assistive personnel (UAP), and supervise this nursing activity.

Other postoperative interventions to prevent complications, such as venous thromboembolism, are similar to those for total hip replacement (see Chapter 20).

Many patients recover fully from hip fracture repair and regain their functional ability. They are typically discharged to their home, rehabilitation unit or center, or a skilled nursing facility for physical and occupational therapy. However, some patients are not able to return to their pre-fracture ADLs and mobility level. These patients usually do not return to their homes and are placed in long-term care facilities. A classic pilot study by Folden and Tappen (2007) identified predictors for patients who are likely to fully recover. They found that balance and cognitive ability were the best predictors.

Other Fractures of the Lower Extremity

Other fractures of the lower extremity may or may not require hospitalization. However, if the patient has severe or multiple fractures, especially with soft-tissue damage, hospital admission is usually required. Patients who have surgery to repair their injury may also be hospitalized. Coordinate care with the physical therapist regarding mobility, transfers, positioning, and ambulation. Collaborate with the case manager regarding placement after discharge. Most patients go home unless there is no support system or additional rehabilitation is needed. Health teaching and ensuring continuity of care are essential.

Fractures of the *lower two thirds of the femur* usually result from trauma often from a motor vehicle crash. A femur fracture is seldom immobilized by casting because the powerful muscles of the thigh become spastic, which causes displacement of bone ends. Extensive hemorrhage can occur with femur fracture.

Surgical treatment is ORIF with nails, rods, or a compression screw. In a few cases in which extensive bone fragmentation or severe tissue trauma is found, external fixation may be employed. Healing time for a femur fracture may be 6 months or longer. Skeletal traction, followed by a full-leg brace or cast, may be used in nonsurgical treatment.

Like most other fractures, *patellar* (knee cap) fractures result from direct impact. The surgeon typically repairs the fracture by closed reduction and casting or internal fixation with screws. A knee immobilizer is used so that the fracture can heal properly.

Trauma to the lower leg most often causes fractures of both the *tibia* and the *fibula*, particularly the lower third, and is often referred to as a “tib-fib” fracture. The major treatment techniques are closed reduction with casting, internal fixation, and external fixation. If closed reduction is used, the patient wears a cast for at least 8 to 10 weeks. Because of poor blood supply to parts of the tibia and fibula, delayed union is not unusual with this type of fracture. Internal fixation with nails or a plate and screws, followed by a long-leg cast for 4 to 6 weeks, is another option. When the fractures cause extensive skin and soft-tissue damage, the initial treatment may be external fixation, often for 6 to 10 weeks, usually followed by application of a cast until the fracture is completely healed. The patient uses ambulatory aids, usually crutches.

Ankle fractures are described by their anatomic place of injury. For example, a bimalleolar (Pott’s) fracture involves the medial malleolus of the tibia and the lateral malleolus of the fibula. The small talus that makes up the rest of the ankle joint may also be broken. An ORIF is usually performed using two incisions—one on the medial (inside) aspect of the ankle and one on the lateral (outer) side. Several screws or nails are placed into the tibia, and a compression plate with multiple screws keeps the fibula in alignment. Weight bearing is restricted until the bone heals.

Treatment of fractures of the foot or phalanges (toes) is similar to that of other fractures, with either closed or open reduction. Phalangeal fractures are more painful than but not as serious as most other types of fractures. Crutches are used for ambulation.

Fractures of the Chest and Pelvis

Chest trauma may cause fractures of the ribs or sternum. The most commonly fractured ribs are numbers 4 through 8. The major concern with rib and sternal fractures is the potential for puncture of the lungs, heart, or arteries by bone fragments or ends. Assess airway, breathing, and circulation status **first** for any patient having chest trauma. Fractures of the lower ribs may damage underlying organs, such as the liver, spleen, or kidneys. These fractures tend to heal on their own without surgical intervention. Patients are often uncomfortable during the healing process and require analgesia. They also have a high risk for pneumonia because of shallow breathing caused by pain on inspiration. Encourage them to breathe normally if possible.

Because the pelvis is very vascular and is close to major organs and blood vessels, associated internal damage is the major focus in fracture management. After head injuries, pelvic fractures are the second most common cause of death from trauma. In young adults, pelvic fractures typically result from motor vehicle crashes or falls from buildings. Falls are the most common cause in older adults. The major concern related to pelvic injury is venous oozing or arterial bleeding. Loss of blood volume leads to hypovolemic shock.

Assess for internal abdominal trauma by checking for blood in the urine and stool and by monitoring the abdomen for the development of rigidity or swelling. The trauma team may use peritoneal lavage, computed tomography (CT) scanning, or ultrasound for assessment of hemorrhage. Ultrasound is noninvasive, rapid, reliable, and cost-effective and can be done at the bedside.

There are many classification systems for pelvic fractures. A system that is particularly useful divides fractures of the pelvis into two broad categories: non-weight-bearing fractures and weight-bearing fractures.

When a *non-weight-bearing* part of the pelvis is fractured, such as one of the pubic rami or the iliac crest, treatment can be as minimal as bedrest on a firm mattress or bed board. This type of fracture can be quite painful, and the patient may need stool softeners to facilitate bowel movements because of hesitancy to move. Well-stabilized fractures usually heal in 2 months.

A *weight-bearing* fracture, such as multiple fractures of the pelvic ring creating instability or a fractured acetabulum, necessitates external fixation or open reduction with internal fixation (ORIF) or both. Progression to weight bearing depends on the stability of the fracture after fixation. Some patients can fully bear weight within days of surgery, whereas others managed with traction may not be able to bear weight for as long as 12 weeks.

Compression Fractures of the Spine

Most vertebral fractures are associated with osteoporosis, metastatic bone cancer, and multiple myeloma. Compression fractures result when trabecular or cancellous bone within the vertebra becomes weakened and causes the vertebral body to collapse. The patient has severe pain, deformity (kyphosis), and occasional neurologic compromise. As discussed in the Osteoporosis section of [Chapter 53](#), the patient’s quality of life is reduced by the impact of this problem.

Nonsurgical management includes bedrest, analgesics, nerve blocks, and physical therapy to maintain muscle strength. Vertebral compression fractures (VCFs) that remain painful and impair mobility may be surgically treated with [vertebroplasty](#) or kyphoplasty. These procedures are minimally invasive techniques in which bone cement is injected through the skin (percutaneously) directly into the fracture site to provide stability and immediate pain relief. [Kyphoplasty](#) includes the additional step of inserting a small balloon into the fracture site and inflating it to contain the cement and to restore height to the vertebra. This procedure is preferred because it reduces the complication of leaking of bone cement outside the vertebral body and it may restore height to decrease kyphosis.

Minimally invasive surgeries can be done in an operating or interventional radiology suite by a surgeon or interventional radiologist. They can be done with moderate sedation or general anesthesia. IV ketorolac (Toradol) may be given before the procedure to reduce inflammation. Large-bore needles are placed into the fracture site using fluoroscopy or computed tomography guidance. Then the deflated balloon is inserted through the needles and inflated in the fracture site, and the cement is injected.

Patients may have the procedures in an ambulatory care setting and return home after 2 to 4 hours or be admitted to the hospital for an overnight stay. [Chart 54-6](#) describes the preoperative and postoperative care for percutaneous interventions for vertebral compression devices.

Before discharge, teach the patient to report any signs or symptoms of infection from puncture sites. Remind him or her to not soak in a bath for 1 week, use analgesics as needed, resume activity, and contact the health care provider for questions or concerns.

CHART 54-6 BEST PRACTICE FOR PATIENT SAFETY & QUALITY CARE

Nursing Care for Patients Having Vertebroplasty or Kyphoplasty

Provide *preoperative care* including:

- Check the patient's coagulation laboratory test results; platelet count should be more than 100,000/mm³.
- Make sure that all anticoagulant drugs were discontinued as requested by the physician.
- Assess and document the patient's neurologic status, especially extremity movement and sensation.
- Assess the patient's pain level.
- Assess the patient's ability to lie prone for at least 1 hour.
- Establish an IV line, and take vital signs.

Provide *postoperative care* including:

- Place the patient in a flat supine position for 1 to 2 hours or as requested by the physician.
- Monitor and record vital signs and frequent neurologic assessments; report any change immediately to the physician.
- Apply an ice pack to the puncture site if needed to relieve pain.
- Assess the patient's pain level, and compare it with the preoperative level; give mild analgesic as needed.
- Monitor for complications such as bleeding at the puncture site or shortness of breath; report these findings immediately if they occur.
- Assist the patient with ambulation.

Before discharge, teach the patient and family the following:

- The patient should avoid driving or operating machinery for the first 24 hours because of drugs used during the procedure.
- Monitor the puncture site for signs of infection, such as redness, pain, swelling, or drainage.
- Keep the dressing dry, and remove it the next day.
- The patient should begin usual activities, including walking the next day, and should slowly increase activity level over the next few days.

Fractures at Other Sites

Because the skull and vertebral column protect the brain and spinal cord, these fractures are described in [Chapters 45 and 47](#). Fractures of the mandible or nose and other facial trauma are also discussed elsewhere in the text.

AMPUTATIONS

An **amputation** is the removal of a part of the body. Advances in microvascular surgical procedures, better use of antibiotic therapy, and improved surgical techniques for traumatic injury and bone cancer all help reduce the number of amputations. The psychosocial aspects of the procedure are as devastating as the physical impairments that result. The loss is complete and permanent and causes a change in body image and often in self-esteem. Collaborate with members of the health care team, including prosthetists, rehabilitation therapists, psychologists, case managers, and physiatrists (rehabilitation physicians), when providing care to the patient who has an amputation.

Pathophysiology

Types of Amputation

Amputations may be elective or traumatic. Most are *elective* and are related to complications of peripheral vascular disease and arteriosclerosis. These complications result in ischemia in distal areas of the *lower extremity*. Diabetes mellitus is often

FIG. 54-11 Common levels of lower extremity amputation.

an underlying cause. Amputation is considered only after other interventions have not restored circulation to the lower extremity, sometimes referred to as *limb salvage procedures* (e.g., percutaneous transluminal angioplasty [PTA]). These procedures are discussed elsewhere in this text.

Traumatic amputations most often result from accidents and are the primary cause of *upper extremity* amputation. A person may clean lawn mower blades or a snow blower without disconnecting the machine. A motor vehicle crash or industrial machine accident may also cause an amputation. The number of traumatic amputations also increases during war as a result of hidden land mines and bombs (e.g., in Iraq), and typically, one or both legs are affected. Thousands of veterans of war in the United States are amputees and have had to adjust to major changes in their lifestyles.

Injury that causes severe crushing of tissues or significant blood vessel damage usually results in amputation to preserve function of the residual limb. The ability to salvage limbs injured related to trauma, however, is increasing. Some body parts that are severed can be reattached or replanted.

Levels of Amputation

Lower extremity (LE) amputations are performed much more frequently than upper extremity amputations. Five types of lower extremity amputations may be performed ([Fig. 54-11](#)).

The loss of any or all of the small toes presents a minor disability. Loss of the great toe is significant because it affects balance, gait, and “push off” ability during walking. Midfoot amputations (e.g., the Lisfranc and the Chopart amputations) and the Syme amputation are common procedures for peripheral vascular disease. In the Syme amputation, most of the foot is removed but the ankle remains. The advantage of this surgery over traditional amputations below the knee is

that weight bearing can occur without the use of a prosthesis and with reduced pain.

An intense effort is made to preserve knee joints with below-the-knee amputation (BKA). When the cause for the amputation extends beyond the knee, above-knee or higher amputations are performed. Hip disarticulation, or removal of the hip joint, and hemipelvectomy (removal of half of the pelvis with the leg) are more common in younger patients than in older ones who cannot easily handle the cumbersome prostheses required for ambulation. The higher the level of amputation, the more energy is required for mobility. These higher-level procedures are typically done for cancer of the bone, osteomyelitis, or trauma as a last resort.

Fewer than 10% of all amputations are upper extremity (UE) amputations. An amputation of any part of the upper extremity is generally more incapacitating than one of the leg. The arms and hands are necessary for ADLs such as feeding, bathing, dressing, and driving a car. In the upper extremity, as much length as possible is saved to maintain function. Early replacement with a prosthetic device is vital for the patient with this type of amputation.

CULTURAL AWARENESS

The incidence of lower extremity amputations is greater in black and Hispanic populations because the incidence of major diseases leading to amputation, such as diabetes and arteriosclerosis, is greater in these populations (Lowe & Tariman, 2008). Limited access to health care for these minority groups may also play a major role in limb loss. Language barriers may also be an obstacle to seeking health care providers.

Complications of Amputation

The most common complications of elective or traumatic amputations are:

- Hemorrhage
- Infection
- Phantom limb pain
- Neuroma
- Flexion contractures

When a person loses part or all of an extremity either by surgery or by trauma, major blood vessels are severed, which causes *bleeding*. If the bleeding is uncontrolled, the patient is at risk for hypovolemic shock and possibly death.

As with any surgical procedure or trauma, *infection* can occur in the wound or the bone (osteomyelitis). The older adult who is malnourished and confused is at the greatest risk because excreta may soil the wound or he or she may remove the dressing and pick at the incision. Preventing infection is a major emphasis in hospitals and other health care settings. In some cases, Medicare will not reimburse for acquired infections.

Phantom limb pain is a frequent complication of amputation. Sensation is felt in the amputated part immediately after surgery and usually diminishes over time. When this sensation persists and is unpleasant or painful, it is referred to as **phantom limb pain (PLP)**. PLP is more common in patients who had chronic limb pain before surgery and less common in those who have traumatic amputations. The patient reports pain in the removed body part shortly after surgery, usually after an above-the-knee amputation (AKA). The pain is often described as intense burning, crushing, or cramping. Some

patients report that the removed part is in a distorted, uncomfortable position. They experience numbness and tingling, referred to as *phantom limb sensation*, as well as pain. Others state that the most distal area of the removed part feels as if it is retracted into the residual limb end. For most patients, the pain is triggered by touching the residual limb or by temperature or barometric pressure changes, concurrent illness, fatigue, anxiety, or stress. Routine activities such as urination can trigger the pain. If pain is long-standing, especially if it existed before the amputation, any stimulus can cause it, including touching any part of the body.

NURSING SAFETY PRIORITY

Action Alert

Recognize the patient's phantom limb pain as real, and treat it aggressively. A combination of drug therapy and complementary and alternative therapies is the best approach for pain management.

Neuroma—a sensitive tumor consisting of damaged nerve cells—forms most often in amputations of the upper extremity but can occur anywhere. The patient may or may not have pain. It is diagnosed by sonography and can be treated either surgically or nonsurgically. Surgery to remove the neuroma may be performed, but it often regrows and is more painful than before the surgery. Nonsurgical modalities include nerve blocks (e.g., with phenol), steroid injections, and cognitive therapies such as hypnosis.
